AGRICULTURE.

iculture.

FROM the great interest attached to its operations and results, Agriculture, at a very early period, began to attract the attention of Mankind. Even in the rudest state, wherever the Human Being is found to observe the institutions of social life, some care is bestowed on the improvement of the soil, and on the preservation of its produce. The wandering shepherd, whether in the wilds of Arabia or in those of the Western continent, has some favoured spot on which he cultivates the natural grasses, and exercises his skill in raising such fruits or herbs as may supply to his household a little variety in their meals, or a remedy in their sickness. The maintenance of his herbs, too, during the inclemency of the seasons, more or less incident to every climate, suggests to him the manifold advantages which may be derived from adding to the fertility of the soil; and hence the gradual transition from the pursuits of a Pastoral society to the more improved habits of the Agriculturist, who enacts laws, fixes barriers around the claims of property, and establishes the grounds of personal rights. For this reason, Ceres, the Goddess of Agriculture among the Ancients, was described as the first legislator, (*legifera*, θεσμοφόρος,) and the Poet accordingly tells us,

> *Prima Ceres unco glebam dimovit aratro,*
> *Prima dedit fruges alimentaque mitia terris,*
> *Prima dedit leges. Cereris sunt omnia munus.*

It is not surprising that the importance of husbandry to the comfort and advancement of the Human race should have led the Mythologists of the East to ascribe divine honours to those persons by whom its various processes were originally introduced. We are told that the Kings of Persia in former days relinquished, once every month, the pomp of sovereignty, and the dainties of the Royal table, and partook of the simple fare of the peasant; preserving thereby the remembrance of the primeval equality which subsisted among Mankind, and affording a sensible token of the high estimation in which Agriculture was held by their people. In modern times, a practice somewhat similar is said to prevail among the Chinese: the monarch every year, at the commencement of Spring, divests himself of all the ensigns of Imperial dignity, puts his hand to the plough, and, offering up a solemn sacrifice, prays for a favourable season and an abundant crop.

History.
The Jews.

Rural Economy divides itself into two great heads. First, the cultivation of the soil for vegetable productions; and, secondly, for the rearing of live stock. The former is more strictly identified with Agriculture properly so called, while the latter comprehends the objects of the breeder, the dairy-man, the shepherd, and even the butcher. But as the improvement of land, including the various Arts by which it is rendered more fertile, applies to the one branch as well as to the other, they are very naturally considered as constituting one subject, united by relations which, resting on their first principles, extend throughout their minutest details. It is our intention, therefore, to embrace in the present Essay both these departments of rural industry; beginning with a Historical outline of the former as it was practised among those ancient nations, whose writings are best known to us.

History of Agriculture.

Of the Jews.

Although the Hebrew Tribes were in general devoted to the pursuits of Agriculture, being by their Religion precluded from commerce with the surrounding States, we are not supplied with such particulars in regard to their practice as might lead us to a just view of their system. The vine and the olive, which, on the calcareous rocks of Palestine, yielded a plentiful return to the cultivator, occupied, it is probable, more attention than the corn which grew in the valleys. This last, watered by the streams which flowed from the neighbouring hills, or cherished by the former and the latter rain, arrived at a speedy maturity under the glowing sun of a climate approaching to the tropical; and, without the exercise of much skill or trouble, filled the barn of the husbandman with an increase of thirty or even sixty fold. The plain through which the Jordan carries its stream, enjoyed in some degree the benefit conferred upon Egypt by the Nile; being partly covered by the annual inundation arising from the melting snows of the Syrian mountains. The septennial rest, too, secured for the land by the institutes of the Divine Legislator, would contribute

Its obscurity.

in no small degree to recruit its powers, and thereby would supersede, to a certain extent, the means usually employed for reviving the strength of an exhausted soil. But it may be sufficient to observe, that the Literature of the Jews, occupied with higher objects, has conveyed to us no record of the manner in which they ploughed and sowed their fields. We find nothing beyond allusions to their rural habits and usages. The Prophet Isaiah, for example, asks, "Doth the ploughman plough all day to sow? Doth he open and break the clods of his ground? When he hath made plain the face thereof, doth he not cast abroad the fitches, and scatter the cummin, and cast in the principal wheat, and the appointed barley, and the rye in their place? For his God doth instruct him to discretion, and doth teach him. For the fitches are not threshed with a threshing instrument, neither is a cart-wheel turned about upon the cummin, but the fitches are beaten out with a staff, and the cummin with a rod. Bread-corn is bruised; because he will not ever be threshing it, nor break it with the wheel of his cart, nor bruise it with his horsemen."*

Under their Kings.

It would appear, however, that Agriculture was held in high esteem even by their Princes. The Crown-lands in the time of King David were managed by seven officers; one was over the storehouses, one over the work and tillage of the ground, one over the vineyards and wine-cellars, one over the olive and oil-stores, and sycamore plantations, one over the herds, one over the camels and asses, and one over the flocks.† King Uzziah, too, "built towers in the desert, and digged many wells; for he had much cattle both in the low country and in the plains; husbandmen also and vine-dressers in the mountains, and in Carmel, for he loved husbandry."‡ We are informed, moreover, that Elijah found Elisha in the field with twelve yoke of oxen and himself with the twelfth. It is well known that both oxen and asses were used in ploughing; but Moses forbade the Jews to yoke an ass with an ox; their step or progress being different, and their labours of course unequal.

Division of lands.

In the later period of their history, the Hebrews, like all other nations of long standing, connived at the possession of large landed estates, although one of their Prophets denounces a curse against those who join house to house, and lay field to field, that they may be placed alone in the midst of the Earth. In the earlier and more simple times, however, it should seem, that while some portion of the land was occupied exclusively by individuals, the greater part was held in common, or in a certain rotation, according to a practice not yet wholly extinct in some districts of Great Britain. This view is confirmed, not only by the regulations laid down by the Jewish Legislator as to herds and flocks, but also by the beautiful story of Ruth, who "came and gleaned in the field after the reapers, and her hap was to light on a part of the field—that is, of the common field—belonging to Boaz."

Of the Egyptians and Assyrians.

The Agriculture of the Egyptians and Assyrians seems to have taken its character from the peculiarities of the country which they respectively occupied. The annual floods which covered their land to a great extent, saved the labour of tillage, and superseded the use of those instruments which, in other parts of the World, were necessary to prepare the soil for receiving the seed. The depositions left by the water formed so rich a mould, that the exertions of the husbandman were confined to the structure of dikes, or the excavation of subsidiary canals. In Egypt the grain sown in the month of November was generally found ripe about the end of March; and during the remainder of the season, pulse followed the grain, and the fruits were succeeded by new flowers. In seconding the liberality of Nature, Man was industrious, and the duty of Agriculture was enforced by various maxims of Religion. The care of tillage, as well as of all other momentous concerns, was originally under the inspection of the Sacerdotal Families, who had of old taught the people how to drain the marshes of the Delta; the smaller mouths of the Nile long bearing the most evident marks of the patient labour which had been necessary to open and keep them clear. Aristotle assures his readers that all the inferior channels by which the river finds its way to the Mediterranean were, χειροποίητα, the work of men's hands.*

Irrigation neglected by the Persians.

The Euphrates performed nearly the same service to the plains of Mesopotamia which the Nile rendered to the valley of Egypt. The Persians, however, originally accustomed to a hilly country, viewed with contempt the magnificent works raised by the Assyrians for directing the current of the river; and the Agriculture and wealth of the Country, accordingly, very soon fell into decay.

Restored by Alexander.

Alexander, whose attention was directed to every species of useful industry, repaired the reservoirs and canals, which he saw to be indispensable in a region where all is desert that cannot be duly supplied with moisture, and where all is exuberant fertility that can be flooded and drained at the proper seasons.† We have already suggested that the great vale of Palestine was probably cultivated in a similar manner by its ancient inhabitants; and, in confirmation of this opinion, we may quote a part of the sacred narrative which relates, that "Lot lifted up his eyes, and beheld all the plain of Jordan, that it was well watered everywhere, before the Lord destroyed Sodom and Gomorrah, even as the garden of the Lord, like the land of Egypt."‡

Of the Greeks.

It is not easy to determine the period at which Agriculture assumed a regular form among the Greeks. Before the arrival of Egyptian colonies the cultivation of the ground might occasionally employ the industry of scattered families; but it is manifest that this valuable Art was not considered as an object of general concern until a much later period. Cecrops is said to have induced the roving hunter and the no less migratory keeper of flocks to relinquish their unsettled mode of life, and to unite in villages under the character of husbandmen. Corn, wine, and oil rewarded their useful labours; and these productions being acquired by common exertion, were regarded, as well as the land itself, as a common property. When a warlike Tribe sallied from their woods and mountains to take possession of a more fertile territory, the soldiers fought and conquered, not for their leaders, but for themselves. The fields acquired by their united valour were considered the inheritance of all who could follow the national banners; and who, at the end of harvest, received their respective shares of the annual produce for the maintenance of their several households. It is true that the wisdom or valour of a Chief was frequently honoured by his Tribe with a valuable allotment of ground set apart for his particular use. This was cultivated, however, not by the hands of his martial associates, who laboured only for the community, but by the captives taken in war, of whom a considerable number was always bestowed upon the General.

Traditional discoveries.

Tradition mentions the original production of the olive, the first culture of the vine, and even the first sowing of corn. The first use of mills for grinding is also recorded. The preparation of a lasting food from milk by converting it into cheese, and the domestication of bees for their honey and wax, were said to have been made known by Aristæus who went from the banks of the river Triton in Africa. So important was this knowledge esteemed by the rude inhabitants of ancient Greece, that in return for it they conferred upon him the honour of being called the son of Apollo, the God of Science; the herdsmen and rustic maidens among whom he had been educated, were, in like manner, raised in imagination to a rank far above that of Human nature, while he himself was at length pronounced to be immortal.[*]

It is remarked by Cicero, that Hesiod in his Poem on Husbandry makes no mention of manure; but Homer expressly speaks of dunging land, as well as of ploughing, sowing, reaping corn, and mowing grass. The culture of the vine, too, was well understood at the same period, and the making of wine was carried through the several processes with much attention and skill. This is evident from various circumstances mentioned by the Poet, and particularly from the age to which wines were kept. Nestor produced some at a sacrifice eleven years old. In the Gardens of Alcinous, the vine is a principal feature taken by itself, while the olive is found only in the orchard with the apple, the pear, the pomegranate, and the fig. Pasturage in all Countries has usually preceded tillage, and we find, accordingly, that in the time of Homer, flocks and herds constituted the principal fund of wealth. Cattle were even the ordinary measure of value in the exchange of commodities. The golden armour of Glaucus, for example, is described as being worth a hundred oxen; the brazen accoutrements of Diomed are estimated at nine; the tripod which was given as the first prize for wrestling at the funeral of Patroclus was valued at twelve oxen; while the female slave, the second prize, was accounted only equal to four. When again Eumæus, in the *Odyssey*, wished to convey an idea of the opulence of Ulysses, he tells neither of the extent of his lands, nor the quantity of his movables, but of his herds and flocks only. Commerce, as we might expect to find at that early period, was carried on almost entirely by barter. In the *Iliad*, for instance, there is mention made of a supply of wine being brought by sea to the Grecian camp; where, says the Poet, it was bought by some with brass, by some with iron, by some with hides, by some with cattle, and by others with slaves.[†]

Incidental notices by Homer.

Implements.

We need scarcely add, that at a period so remote, the implements of husbandry were extremely imperfect; the plough itself, the most useful of them all, being composed entirely of wood. The Greeks employed in the time of Hesiod the invention of shears for depriving the sheep of their wool; having formerly waited the season of its annual separation by Nature. Barley was the principal produce of their fields, and furnished the ordinary food both of men and of horses. The invention of mills was unknown, and the grain underwent several tedious operations in order to facilitate the bruising of it between two large stones with the hand.

Dangers of Northern Greek Agriculture according to Xenophon.

Xenophon has bequeathed to posterity some remarks on the state of Agriculture in his native Country. He admits that, in most parts of Greece, soil and climate did much for the cultivator: but it is not concealed that, amid the ravages of war and sedition, the exertions of Art were hasty and unsystematical. He has, in fact, drawn a very unfavourable picture of the life of a husbandman in two of its largest and most fruitful Provinces. It occurs in the description of an entertainment given by the officers of the Cyreian army, while encamped near Cotyora, to the ministers of Corylas, Prince of Paphlagonia. Among both Greeks and Barbarians, as among the Eastern nations at this day, the meal was commonly succeeded by dances and pantomimes. After one of these movements, performed to the sound of the flute by two Thracians as targeteers, some Ænians and Magnetes, people of the Thessalian borders, stepped forward, and in the full armour of the phalanx exhibited the dance called the Carpæan. The manner of it, says Xenophon, was this: "While the pantomimic dance was proceeding to the music of the flute, one advances as a husbandman. Grounding his arms, he sows and drives his oxen, often looking round as if in fear. Another approaches as a robber. The husbandman seeing him runs to his arms, and a combat ensues. The robber prevails, binds the Agriculturist, and drives off the cattle. Then the dance is varied; the husbandman is victorious, binds the robber's hands behind him, yokes him with the oxen, and drives off altogether."[*]

Less perilous in Southern Greece.

In Laconia and Attica, as well as some other parts of Southern Greece, the situation of the cultivator was unquestionably less unfortunate. It was not at all times necessary for the ploughman to carry arms, while he and his cattle were sufficiently protected from at least the solitary robber. Yet, if we consider the state of the Country at large, we shall hardly wonder if the notices on Agriculture, left by the Greeks of the Republican times, are not among the most valuable of their writings.

Hesiod's remark on ploughing illustrates Scripture.

There is an expression in Hesiod,—whose Poem, on the *Works and Days*, is, perhaps, the most complete Treatise that has come down to us on the Agriculture of ancient Greece—which helps to explain a passage in the Gospel not generally nor sufficiently understood; "He that putteth his hand to the plough and looketh back, is not fit for the Kingdom of Heaven." Describing the character of a good ploughman, the Ascræan remarks, that he must not let his eye wander about, nor be absent in mind, but be careful that he may cut a straight furrow, and not sow the same twice.[†] The imperfect instrument called a plough in those days required incessant attention, being guided with only one hand; and it is not improbable that, in some parts of the Country, it was the practice to deposit the seed in the furrow with the other hand, while the process of ploughing was going on. In this case a vigilant eye would be still more indispensable.

Of the Romans.

If there be any deficiency in the writings of the Greeks on the subject of Agriculture, there is an ample compensation to be found in those of the Romans. In the Works of Cato, Varro, Virgil, Columella, Pliny, and Palladius, we possess all the information which might be required either to gratify curiosity or to aid the History of an important Art; and as it has been remarked, instead of schemes produced by a lively imagination, which we receive but too frequently from authors of genius unacquainted with the practice of Agriculture, we have good reason to believe that they deliver in their volumes a genuine account of the most approved usages, of which they themselves had experienced the utility. It is asserted, too, that if in the theory of their profession the Roman cultivators were inferior to the Moderns, they were greatly superior to our best improvers in attention to circumstances, in exactness of execution, and in economical management.[*]

Causes of Roman superiority.

Mode of farming lands.

In the first Ages of the Commonwealth the lands were occupied and cultivated by the proprietors themselves, men accustomed to the activity and precision of military life; and as this state of things continued four or five centuries, it was probably the chief cause of the Agricultural eminence of the Romans. An observation made by Pliny confirms this supposition; for he assures us that his Countrymen, in early times, ploughed their fields with the same diligence that they pitched their camps, and sowed their corn with the same care that they arranged their armies in the day of battle. Afterwards, when Rome extended her conquests, and acquired large territories, individuals became owners of wide domains, the culture of which fell into inferior hands. Such estates were either committed to the management of responsible servants, who had under them a great number of slaves, or let out to farmers, who occupied a portion of the soil on certain conditions and for a limited period. Generally speaking, the stock on the farm belonged to the landlord, and the cultivator received only a specific portion of the produce in return for his labour and superintendence. In reference to this position, the latter was called *politor* or *polintor*, the dresser of the soil; while, from being in a kind of copartnership with his superior, and receiving a share of the produce, he was sometimes denominated *partuarius*. Cato has recorded that, in the best land, the *politor* obtained the ninth basket; in the second kind of land, he got the eighth; in the third description he received the seventh; and in a still inferior, he was remunerated by being allowed to retain the fifth.

Columella's instructions to landlords.

The *Coloni*, or farmers properly so called, seem to have paid rents for their ground in a manner nearly similar to that which is observed among ourselves. The directions given by Columella to a landlord concerning the mode of treating that class of men are curious as well as important, and not altogether inapplicable at the present day. He ought, says he, to conduct himself towards his tenants with gentleness, should show himself not difficult to please, and be more solicitous to exact culture than rent, because this is less severe, and, upon the whole, more advantageous. For when a field is carefully cultivated, it for the most part brings profit, never loss, except when assaulted by a storm or pillagers. Neither should the landlord be very tenacious of his right in every thing to which the farmer is bound, particularly as to days of payment, and demanding the wood and other small things which he is obliged to furnish, the care of which is greater trouble than expense to the rustics. Nor is every penalty in our power to be exacted, for our ancestors were of opinion that the rigour of the law is the greatest oppression. On the other hand the landlord ought not to be entirely negligent in this matter; because it is certainly true what Alpheus the usurer was wont to say, that "good debts become bad ones by not being called for."[*]

Agricultural servants.

Price of labour.

The servants employed in Roman Agriculture were either freemen or slaves. When the proprietor lived on the farm and directed its culture, these were, of course, under his own management; in other cases there was an overseer to whom all the labourers were subordinate. This agent was generally a person who had received some education, although Columella[*] thinks that he might transact business very well without the use of letters; and Cornelius Celsus adds, that the illiterate bailiff is to be preferred, because he will bring money to his master oftener than his book, since being ignorant of figures, he will be the less capable to contrive accounts and the more afraid to trust others. As far as we can compare prices in ancient and modern times, it does not appear that Agricultural labour was cheap among the Romans, even when they employed the hands of slaves. In the days of Cato, the price of a slave was about £50; in those of Columella, it had risen to £60; being the value of eight acres of good land. An expert vine-dresser cost £66. 13*s*. 4*d*., and a ploughman about the same sum. The interest of money at that period was 6 per cent.; therefore in estimating the expense of farm-labour, the work of a slave, being a perishable commodity, ought to be rated at not less than 12 per cent. on his purchase money. Hence one who cost £60 must be charged at £7. 4*s*. yearly, besides his clothing and maintenance.[†]

Ploughing.

Of all Agricultural operations, the Romans attached the greatest importance to ploughing. What, says Cato, is the best culture of land? Good ploughing. What is the next best? Ploughing. What is the third? The application of manure. In the strong loamy soils of Italy the maxim of this sage Agriculturist could not be applied too extensively, because the richness of such land required to be excited into energy rather than to have its powers increased. In most cases a crop and a year's fallow succeeded each other; although when manure could be obtained, two crops or more were taken in succession; and in certain fertile districts described by Pliny as favourable for barley, a crop was raised every year. In fallowing, the lands were first ploughed after the crop was removed, generally in August; they were again cross-ploughed in Spring, and at least a third time before sowing. In other cases, however, there were no limits to this operation; the object being, as Theophrastus observes, "to let the earth feel the cold of Winter and the heat of Summer; to invert the soil and render it free, light, and clear of weeds, so that it might afford a full supply of nourishment to the plants."[‡]

Manuring.

The Roman authors lay great stress on the use of proper manure. Pliny reminds his readers that in Homer an old King is represented as spreading dung on his fields with his own hands. Augeas, a personage too of Royal station, is said to have been the first among the Greeks who discovered this method of aiding the resources of land. In Italy, where Hercules is reported to have divulged the secret, a lasting fame was conferred by his subjects upon King Sterculius for communicating the invention to the practical husbandman. On this head the ancient farmers on the Tiber and the Po had the merit of setting an example to future Ages, which cannot be too closely followed. They were so sensible of the advantage arising from manuring their grounds, that they were most assiduous in collecting every material which seemed proper for the purpose. Besides the usual resources supplied by the stable and fold, they gathered ashes, shrubs, stubble, burned the branches of trees, and even heaped together different kinds of earth. "You may make manure," says Cato, "of lupines, bean-stalks, chaff, holm, and oak-leaves. From the corn-fields pull out dwarf alder, hemlock, and all the tall grass and reeds in the willow plantations, and lay them below the sheep and cows." "I am not ignorant," says Columella, "that there are some farms in the country on which neither the dung of cattle nor of birds is to be procured; and yet, even in such places, he is a slothful cultivator who can find no manure. He may collect any kind of leaves, the cuttings of briers, and the rakings of highways, and mix them with the cleanings of the court-yard."[*]

[‡] Theoph. *de caus. Plant.* lib. iii. c. 25. Cato, c. 61. *Quid est agrum bene colere? bene arare. Quid secundum? arare. Quid tertium? stercorare.* See also Pliny, book xviii c. 19.

Mixture of soils.

But the Ancients were not only very diligent in the use of every animal and vegetable substance which might minister to the improvement of their lands, they also, as we are informed by Theophrastus, were wont to mix together earths of different qualities, light with heavy, fat with lean, and, in short, all those which displayed any contrariety in their nature. This mixture, he adds, not only supplies what is wanting in point of depth, but also renders the soil with which another is mingled much more powerful; so that what is worn out, being mixed with any fertile kind of earth, begins again to carry crops, as if renewed; and what is naturally barren, such as clay, is rendered fruitful by the addition of ingredients possessing an opposite quality. In fact, this mixture, when judiciously made, is considered a complete substitute for manure. The people of Megara, besides adopting the process now described, were wont to trench their fields every fifth or sixth year; and digging as deep as the rain is understood to penetrate, they brought the bottom of their soil to the top; it being a maxim with them that the particles of earth proper for the nourishment of plants, are always carried downwards as far as the surface water descends.[†]

Marl.

Marl was known to the earlier authors of Rome, but was not used in Italy. It is mentioned by Pliny as occurring in Britain and Gaul, and is described by him as being like the kernels in animal bodies which are enervated by fatness. It was employed, he subjoins, as a manure by the Greeks, "for what is there which they have not tried?" Varro relates that, when he marched an army to the Rhine in Transalpine Gaul, he passed through Countries where he saw the fields manured with a white fossil clay, which must have been either marl or chalk.

Sowing.

Sowing was performed with the hand from a basket, as in modern times; the hand, as Pliny remarks, moving with the step, and always with the right foot. The corn and leguminous seeds were covered with the plough, and sometimes so as to rise in drills; the smaller seeds were earthed with the hoe and rake.

Reaping.

Varro mentions three modes of conducting the operation of reaping, which, in order to avoid the hazard attending boisterous weather, the best authors recommended to be done before the crops were fully ripened. The first method was to cut close to the ground with hooks; the second was to cut off the ears with a curved stick having a saw attached; and the third was to cut the stalks in the middle, leaving the lower part, or stubble, to be gathered afterwards. To these modes Pliny adds that of pulling up by the roots; and remarks generally, that where they cover their houses with straw, they cut high to preserve this of as great a length as possible, but that where fodder is scarce they cut low with the view of securing an addition to their forage.

By Machinery.

A reaping-machine, used in the plains of Gaul, is described by Palladius in the following terms. The Gauls, says he, "use this quick way of reaping, and without reapers cut large fields with one ox in a single day. For this purpose a machine is made supported upon two wheels; the surface has boards erected at the side, which sloping outwards, make a wider space above. The board on the fore part is lower than the others; upon it there are a great many small teeth, set in a row, answering to the height of the corn, and turned upwards at the ends. At the back part of the machine two short shafts are fixed, like the poles of a litter; to these an ox is yoked with his head to the machine, and the yoke and traces likewise turned the contrary way. When this piece of mechanism is pushed through the standing corn, all the ears are enclosed by the teeth, and heaped up in the hollow part of it, being cut off from the straw which is left behind, the driver setting it higher or lower as he finds it necessary; and thus by a few goings and returnings, the whole field is reaped. The machine does very well in plain smooth lands, and in all places where the straw is not considered of any value." A conjectural delineation of this instrument is given by Lasteyrie, in his Work entitled *Collection des Machines*. (See fig. 1.)

Carrying.

The Romans, says Mr. Loudon, did not bind their corn into sheaves as is customary in Northern climates. When cut it was in general carried directly to the *area* to be thrashed, or if the ears only were cropped, they were sent in baskets to the barn. Among the Jews, Egyptians, and Greeks, the corn was bound in sheaves; or at least some kinds were so treated, as we learn from the story of Ruth, who gleaned "among the sheaves;" from Joseph's dream in which his "sheaf arose;" and from the harvest represented by Homer on one of the compartments of Achilles's shield.[*]

Threshing.

Threshing was performed in the *area* or threshing-floor, which was a circular piece of ground, fifty or sixty feet in diameter, with a smooth, hard surface. The floor, indeed, was generally made of wrought clay mixed with the lees of oil, which increased its tenacity; sometimes it was even paved. It was usually selected in the neighbourhood of the *nubilarium* or barn, in order that, when a sudden shower happened during the process of threshing, the ears might be removed thither out of the reach of damage. The corn being spread over this surface, a foot or two in thickness, was beaten out either by the hoofs of cattle, or by dragging over it a machine composed of wood and iron, and surmounted by a considerable weight. Occasionally rods or flails were used for the same purpose, while the Indian corn, *far*, or maize, was picked with the hand, or pressed through a small mill.

[*] *Encyclopædia of Agriculture*, p. 26.

Winnowing.

The produce of the threshing-floor was winnowed or purified from the husks and chaff by being thrown from one part of the barn to another across a current of wind. The instrument used for this end was a kind of shovel called *ventilabrum;* and to supply the absence of wind it was customary to substitute an implement called *vannus*, the origin, perhaps, of the modern and much more complex machine denominated fanners.

Ignorance of Theory.

It is remarkable that, in regard to the practical knowledge of Agriculture, the Romans were very little inferior to the most intelligent among husbandmen in our own days. They were indeed extremely deficient in point of Science, being unable to give a reason for their best established usages which did not terminate in simple experience or accident. They knew nothing of Chemistry or Physiology, were unacquainted with the analysis of soils or manures, and were especially ignorant of those principles in Mechanics which determine the strength of materials, and the application of force. Again, in accounting for many of the most ordinary phenomena of Nature, they had recourse to supernatural and imaginary causes. In the rude periods of Society, Good and Evil Spirits are supposed to take a concern in every thing; and hence the absurd superstitions of the Egyptians, and the equally whimsical ceremonies of the Greeks, to procure their favour or avert their malign influence. Hesiod, accordingly, considered it of not more importance to describe what works were to be done, than to point out the lucky days for their performance. Homer, Aristotle, Theophrastus, and all the Greek authors, are more or less tinctured with this belief, so prevalent in the darker Ages of remote antiquity. Nor were the Romans in this respect less enthralled than the ingenious People from whom they borrowed the most valuable part of their knowledge. The empire of superstition extended over all their undertakings, and none more completely than the important pursuits of Agriculture. In some cases Imagination seized the reins which should never be taken out of the hands of Reason and Experience; and hence both Virgil and Pliny venture upon statements in regard to heterogeneous grafting, the spontaneous generation and transmutation of plants, the influence of lunar days, and the impregnation of animals by certain winds, which every Physiologist knows to be altogether inconsistent with the laws of Nature.

Superstitions.

Progress,

It is a question of curiosity rather than of Scientific importance, to determine how much Agriculture owed to the Romans, and to what extent they improved upon the usages of the Greeks and Egyptians. As the writers of Italy refer in most cases to authors who flourished at an earlier period among their neighbours beyond the Adriatic, it is probable that the leading principles of the Art were borrowed from Greece. But there can be no doubt that the progress of the Roman arms in Helvetia, Germany, and Britain extended the knowledge of tillage among barbarous Tribes by whom it was formerly unknown or neglected. The conquerors imposed a tribute of corn on the vanquished Provinces, which compelled the natives to cultivate the soil. Large fleets sailed from the shores of Britain laden with grain for the Imperial stores in various parts of their extensive dominions. Egypt, too, with Sicily and Africa, contributed immensely to feed the armies and luxurious citizens of the proud Republic, until at length, by a just retribution, she found herself at the mercy of the very Countries which she had subdued. Agriculture which flourished abroad decayed gradually at home. The great men in Rome, trusting to their revenue from the Provinces, neglected the improvement of their estates in Italy; and while their lands became less productive, they insisted upon higher rents. The farmer, sinking under broken spirits and a diminishing capital, imitated his landlord in idleness and rapacity. The Civil wars which ensued, the tyranny of the Emperors, and at length the removal of the seat of Government to Constantinople, paved the way for the Northern invaders, and consequently for the downfal of Agriculture, and of every useful or elegant Art.

History.—The Romans.

and decline of Roman Agriculture.

Implements.

In regard to implements for the uses of husbandry, the Romans possessed several, of which neither the form nor the purpose is now distinctly known. We find mentioned in their Agricultural authors the *aratrum*, the *irpex*, or *urpex*, the *crates*, the *rustrum*, the *bidens*, the *securis*, the *dolabra*, the *ligo*, the *pala*, the *sarculum*, the *marra*. By the first, as every one knows, is meant the plough, of which it appears there were varieties among the cultivators of ancient Italy. The other instruments, in their order, correspond to a weeder or breaker, a harrow, a rake, a toothed hoe, an axe or pruning-hook, a mattock, a spade, a small shovel, a hand-hoe, a scraper or Dutch hoe. In some cases these are only approximations; for we find no small difficulty in reconciling the descriptions of the several authors who have written on the rural economy of the Ancients, as well as in comparing the instruments they delineate to the more artificial tools of modern times.*

The plough.

As the plough is the most important of all Agricultural machines, we may be indulged in a few details respecting its form, more especially as Virgil, the Prince of Roman Poets, has not disdained to supply us with some particulars in regard to its construction.

> *Continuo in silvis magnâ vi flexa domatur*
> *In burim, et curvi formam accipit ulmus aratri.*
> *Huic a stirpe, pedes, temo protentus, in octo;*
> *Binæ aures, duplici aptantur dentalia dorso.*
> *Cæditur et tilia ante jugo levis, altaque fagus,*
> *Stivaque quæ currus a tergo torqueat imos;*
> *Et, suspensa focis explorat robora fumus.*
>
> *Geor.* i. v. 169.

> Young elms with easy force in copses bow,
> Fit for the figure of the crooked plough.
> Of eight feet long a fastened beam prepare:
> On either side the head produce an ear,
> And sink a socket for the shining share.
> Of beech the plough-tail and the bending yoke,
> Of softer linden hardened in the smoke.
>
> Dryden.

It is asserted in a Work entitled the *Husbandry of the Ancients*, that the Romans had all the different kinds of ploughs that we have at present in Europe, though perhaps not so exactly constructed. "They had ploughs without mould-boards, and ploughs with mould-boards; they had ploughs without coulters, and ploughs with coulters; they had ploughs without wheels, and ploughs with wheels; they had broad pointed shares, and narrow-pointed shares; they even had what I have not yet met with amongst the Moderns, shares not only with sharp sides and points, but also with high raised cutting tops. Were we well acquainted with the construction of all these, perhaps it would be found that the improvements made by the Moderns in this article, are not so great as many persons are apt to imagine." (See fig. 2, 3, 4.)

---

* These, says the author of the *Georgics*, are the rural arms, without which crops can neither be sown nor reaped.

> *Queis sine, nec potuere seri, nec surgere, messes:*
> *Vomis, et inflexi primum grave robur aratri,*
> *Tardaque Eleusinæ Matris volventia plaustra,*
> *Tribulaque, traheæque, et iniquo pondere rastri,*
> *Virgæ præterea Celei vilisque supellex,*
> *Arbuteæ crates, et mystica vannus Iacchi.* lib. i. 164.

Day observations.

We have already alluded to the superstitions of the Ancients in respect to fortunate and unfortunate, and the extent to which those feelings were admitted in the processes of Agriculture. This is one instance among many wherein we discover a striking contrast between the practical good sense of a great People, and their speculative absurdity in matters of belief. Virgil, for example, in the very middle of his precepts for sowing, planting, manuring, weeding, and reaping, inserts the following admonition for the use of the Italian peasants.

Ipsa dies alios alio dedit ordine Luna
Felices operum: quintam fuge; pallidus Orcus,
Eumenidesque satæ: tum partu Terra nefando
Cœumque Iapetumque creat, sævumque Typhoëa,
Et conjuratos cœlum rescindere fratres.

* * * *

Septima post decimam felix, et ponere vitem,
Et prensos domitare boves, et licia telæ
Addere: nona fugæ melior, contraria furtis.
Geor. i. v. 276.

The lucky days in each revolving moon
For labour choose; the fifth be sure to shun:
That gave the Furies and pale Pluto birth,
And arm'd against the skies the Sons of Earth.

* * * *

The seventh is next the tenth the best to join
Young oxen to the yoke, and plant the vine.
The ninth is good for travel, bad for theft.
Dryden.

Omens of weather.

Amid the indications of the weather, too, as depending upon the aspect of the heavenly bodies, the same delightful author mingles his political regrets and superstitions. The beauty of the verse will excuse us in the eye of every reader of taste for this concluding extract from the Agricultural Poem of Virgil.

Sol tibi signa dabit: Solem quis dicere falsum
Audeat? Ille etiam cæcos instare tumultus
Sæpe monet, fraudemque et operta tumescere bella,
Ille etiam exstincto miseratus Cæsare Romam;
Quum caput obscurâ nitidum ferrugine texit,
Impiaque æternam timuerunt sæcula noctem.
lib. i. v. 463.

The sun reveals the secrets of the sky;
And who dares give the source of light the lie?
The change of empires often he declares,
Fierce tumults, hidden treasons, open wars.
He first the fate of Cæsar did foretell,
And pitied Rome when Rome in Cæsar fell;
In iron clouds concealed the public light,
And impious mortals feared eternal night.
Dryden.

Italy.

The decline of the Roman power was accompanied with the neglect of Agriculture in almost all the Countries which had submitted to the arms of the Commonwealth. Little is known of the condition of this Art in Italy during the long period of twelve hundred years, as it was not till the beginning of the XIVth century that any Work appeared on that important branch of industry. About the era now specified, a Treatise entitled *Ruralium Commodorum* was written by Crescentio, a Senator of Bologna, and afterwards published in 1471. He was soon followed by several of his Countrymen, among whom Tatti, Stephano, Augustino Gallo, Sansovino, Lauro, and Torelli, deserve to be mentioned with applause. From some records, however, which have escaped the ravages of time, it appears that irrigation was practised nearly two centuries before the earliest of the dates now mentioned. The Monks of Chiaravalle had set an example in this species of improvement, and had become so celebrated in quality of hydraulic engineers as to be employed by the Emperor Frederic I. The volume of Crescentio is, in great part, a compilation from the older Roman authors, such as Cato, Varro, and Pliny; but being illustrated with figures, is valuable because it enables us to form some notion of the implements then in use. The plough is drawn by only one ox; but other kinds, which must have been drawn by two, and even by four, are described at some length. The Political troubles which so long agitated the fine Provinces Southward of the Alps, prevented them from profiting by the revival of the Arts in other parts of Europe; and hence, at the present day, although Italy can boast of a rich soil and a favourable climate, her inhabitants have no where entitled themselves to the reputation of being good farmers.*

France.

France, too, overrun by the Northern Barbarians, or by the Tribes of native Germans hardly more civilized, was long doomed to witness the decline of that pursuit upon the success of which the prosperity of all others is more or less suspended. In the XIIth century, the care bestowed by some leading Churchmen upon the produce of the soil was rewarded by a considerable melioration in the state of the peasantry, as well as in the value of lands. Four hundred years later, the first Agricultural Work produced in France made its appearance, under the title of *Les Moyens de devenir riche*, composed by Bernard de Pallisy, a potter, who is said to have written on various other subjects. Under the auspicious reign of Henry IV. great exertions were made for the improvement of the Country in general, amidst which the interests of rural economy were not forgotten. Sully asserts, in his *Memoirs*, that, in his time, France abounded with corn, grain, pulse, wine, cider, flax, hemp, salt, wood, oil, drugs for dyeing, cattle great and small, and every thing else, whether necessary or convenient for life, both for home consumption and exportation.

Great changes for the better were made in France during the last century. The celebrated Economists created a taste for the Art, and Agricultural Societies were every where established under the sanction of the Government. Those of Paris, Lyons, Amiens, and Bourdeaux distinguished themselves by the publication of some valuable *Memoirs*. The name of Buffon, too, gave reputation to this study, and various other writers contributed to make it popular. Chaptal informs us that essential improvements have been introduced since the Revolution. Crops of every kind, says he, cover the soil; numerous and robust animals are employed in labouring it, and they also enrich it by their manure. The country population are lodged in commodious houses, decently clothed, and abundantly nourished with wholesome food. We are not however to suppose, he observes, that the Agriculture of France has arrived at perfection; much still remains to be done; new plans of improvement should be more generally introduced; and a greater quantity of live stock is wanted for every Province, except two or three, which abound in natural meadows Few domains have more than half the requisite number of labouring cattle; the necessary consequence of which is a deficiency of labour, of manure, and of crop. The only mode of remedying these evils is to multiply the artificial pastures, and increase the cultivation of plants destined for forage. The rich inhabitants of France have already adopted these principles; but they have not not yet found their way among the lowest class of cultivators. According to M. Dupin, four-fifths of the peasantry of France are proprietors of land, which they cultivate themselves; and although Knowledge is rapidly advancing, they are still very ignorant. It is readily admitted, too, that France is still miserably deficient in the better kind of Agricultural instruments.

---

* Loudon, p. 34. Harte, *Essays on Husbandry*.

Germany.

As Germany had not shared so extensively as some other European Countries in the civilization diffused by the Romans, the reaction occasioned by the desolating wars of the IVth and Vth centuries was less deeply felt in the Provinces beyond the Rhine. Accordingly, it is not till the beginning of the XVIth century that we can discover any symptom of Agricultural advancement among the numerous Nations which extend from the borders of France to the shores of the Baltic. The earliest Work on Husbandry, by a German author, is the Treatise *De Re Rusticâ*, by Conradus Heresbachius, published about the year 1576. It is composed in the form of Dialogue, and contains an outline of the opinions and precepts delivered by the Ancients, from Hesiod down to Pliny; being, in fact, an Essay compiled from the literary materials of former Ages, rather than a Treatise on the Art as it appeared before his eyes, or which was meant to improve either its theory or practice.

Britain.

In relation to Britain, although it is certain that Agriculture was not wholly unknown before the Roman invasion, it is difficult to say when it was first introduced, or how far it had then advanced. Both the Greeks and Phœnicians visited this island long before the Legions landed on its shores with a view to conquest; but as their visits were only transient, and for the sake of trade, it is uncertain whether they took the trouble to instruct the natives how to cultivate the soil. It is more probable that the knowledge of this important Art was brought hither by some of those Colonies which are known to have passed over from the coast of Gaul. These emigrants having been employed in Agriculture in their own Country, pursued the same employment in their new settlements. This was the opinion of Cæsar. "The sea-coasts," he observed, "are inhabited by Colonies from Belgium, which, having established themselves in Britain, began to cultivate the land."[*]

Introduction of Agriculture.

Agriculture, we may therefore presume, was little known in this island till about a hundred and fifty years before the beginning of the Christian Era, when great multitudes of Celtic Gauls, being expelled from their native seats between the Rhine and the Seine by the German *Belgæ*, took shelter in the South of England, where they formed several small States. These communities received reinforcements from time to time from the same coasts, whose inhabitants were then called *Belgæ*, and practised husbandry; a way of life which they were encouraged to pursue in Britain by the fertility of the soil, which produced all kinds of grain in great plenty and perfection. If we could depend on the testimony of Geoffry of Monmouth, we should be led to think that Agriculture had been greatly prized in this Country several Ages before the period abovementioned, for he acquaints us that, by one of the laws of Dunwallo Molmutius—who is said to have reigned over all Britain about five centuries before the birth of Christ—it was declared that the ploughs of the husbandmen, as well as the Temples of the Gods, should be held as sanctuaries to such criminals as fled to them for protection.[*] But this is thought to be only one of the many fables related by that author, the law to which he alludes being of a much later date: and upon the whole the truth seems to be that, though Agriculture might be practised a little by a few of the more ancient Britons, yet it was chiefly introduced by the Belgic Gauls, about a century before the first Roman invasion, and almost wholly confined to them till after that event.

Early manures.

Marl.

Lime.

Very few of the peculiar practices of the most ancient British husbandmen are preserved in History. It appears that they were not unacquainted with the use of manures, for renewing and increasing the fertility of their grounds; and that, besides those which were common to other Countries, they had one peculiar to themselves and the Gauls. This was marl, which we have already noticed in the quotation from Pliny. The same writer, after describing different kinds of that substance, remarks, "of those which are esteemed the richest, the white ones are most valued, and of these there are several species. First, one which hath a most sharp and piquant taste; another kind is the white chalky marl, much used by silversmiths: for this they are sometimes obliged to sink shafts one hundred feet deep, when they find the vein spreading broader, as in other mines. It is this kind of marl which is most used in Britain. Its effects are found to continue eighty years; and no man was ever known to have manured the same field with this marl twice in his lifetime."[†] It is highly probable that lime was also employed for the same purpose by our remote ancestors, because we know with certainty that it was so used in Gaul, from whence the knowledge of it might easily be conveyed.

Diodorus Siculus.

The instruments and method of ploughing, sowing, and reaping in this Country were no doubt the same as among the Gauls from whom they were derived; and these probably were not very different from such as were used in Italy during the times of which the practice is so fully described by the Roman writers on Agriculture. Diodorus Siculus has recorded some remarkable particulars relating to the manner in which the most ancient British husbandmen preserved their grain, after it was reaped, and prepared it for use. They cut the ears from the stubble, says he, and lay them up for preservation in subterraneous caves or granaries. From thence they relate that, in very remote times, they used to take a certain quantity of these ears every day, and having dried and bruised the grains, made a kind of food of them for immediate eating.[‡] Though these methods were very slovenly and imperfect, they were not peculiar to the old Britons, but were practised by other nations, and some vestiges of them were remaining not long ago in the Western Isles of Scotland.*

[‡] Lib. v.

Encouragement given by the Romans to British Agriculture.

As soon as the Romans had attained a firm establishment in Britain, Agriculture began to be improved and extended; it being an Art in which that renowned people greatly delighted, and which they encouraged in all the Provinces of their Empire. When, according to Cato, his Countrymen designed to bestow the highest praise on a good man, they used to say, "he understands Agriculture well, and is an excellent husbandman; for this was esteemed among them the greatest and most honourable character." As soon, therefore, as the soldiers of the Republic had subdued some of the British States, they endeavoured by various means to induce their new subjects to cultivate their lands, in order to render their conquest more valuable. In fact, the tribute of a certain quantity of corn which they imposed on their vassals, compelled the mass of the people to apply to Agriculture. The veteran colonists too, who were not less expert at guiding the plough than wielding the sword, set before the natives an example both of the most improved method, and the manifold advantages of this branch of industry. In short, the Romans by their power and policy, and more especially by their superior knowledge, so completely reconciled the Britons to the cultivation of their lands, that in a little time this Island became one of the most plentiful Provinces of the Empire, and not only produced a sufficient quantity of corn for the support of its own inhabitants and the Roman troops, but afforded every year a very great surplus for exportation. This became an object of so great importance that a fleet of ships was provided for the particular service of carrying corn from Albion to granaries on the opposite coasts, whence it was conveyed into Germany and other Countries for the use of the armies. We are informed by Ammianus Marcellinus, that the Emperor Julian having collected prodigious quantities of timber from the banks of the Rhine, built a fleet of a hundred ships, larger than the common barks, which he sent to Britain, in order to bring corn thence. When it arrived, he sent it up the Rhine in boats, and furnished the inhabitants of those towns and Countries which had been plundered by the enemy with a sufficient quantity to support them during the Winter, to sow their lands in the Spring, and to maintain them till next harvest.†

Obscurity of its progress.

We have sufficient evidence that the knowledge of husbandry, and indeed of all the other Arts, entered Britain at the South-Eastern corner, and travelled by slow and gradual steps towards the North-West; but it is difficult to trace the progress of these Arts, or to discover how far they had advanced at any given period. With regard to Agriculture we are assured by a contemporary author, that in the beginning of the IIId Century, it had not proceeded further than the wall of Hadrian. In the year 207, when the Emperor Severus invaded Caledonia, we are told that the natives "inhabited uncultivated mountains, or desert marshy plains; that they had neither walls, towns, nor cultivated lands, but that they lived on the flesh and milk of their flocks and herds, or what they got by plunder, or catched in hunting, or on the fruits of trees." The Mæatæ and Caledonians having been obliged by Severus to yield up a part of their Country to the Romans, that industrious people, in the course of the IIId Century, built several towns and stations, constructed highways, cut down woods, drained marshes, and introduced Agriculture into the country between the walls, many parts of which are very fertile and fit for tillage. Although they never formed any large establishment Northward of the wall which joined the firths of Forth and Clyde, yet many of them, as well as of the Provincial Britons, retired into Caledonia at different times, particularly about the end of the IIId Century, during the heat of the Diocletian Persecution. It is therefore highly probable that these refugees instructed the people among whom they settled not only in their Religion, but also in their Arts, and especially in that of Agriculture. The name which was given to the Caledonians of the Eastern coast by those of the Western, was *Cruitnich*, which signifies corn-eaters, a convincing proof that the latter were husbandmen. From other facts it is clear that in the beginning of the Vth Century the Scots of the mountains lived partly upon meal; a kind of food to which they had been absolute strangers about two hundred years before, when they were first startled by the appearance of the Roman Eagles under Severus.

Its decline after the withdrawal of the Romans.

When the Roman power declined in Britain, Agriculture with the other Arts of civilized life fell into comparative neglect. This was not so much owing, however, to want of skill in the native husbandmen, as to the frequent incursions of the Saxons, who had already begun to enrich themselves with the plunder of the English; and who, together with the Scots and Picts from the North, not only destroyed the fruits of their labours, but also disturbed them in the exercise of their industry. We need not be surprised, therefore, that the posterity of the ancient Britons became rather unskilful Agriculturists, and that they thenceforth applied themselves more to pasturage, than to the culture of an unprotected soil. It is clear, notwithstanding, that, even in its most depressed condition, Agriculture was regarded by them as worthy of attention in a legal point of view, and hence was made the object of several characteristic enactments. They prohibited, for example, the use of horses, mares, or cows in the plough, and restricted the farmer to certain yokes of oxen. Their implements, it is true, were very slight and inartificial; for it was regulated by statute that no man should undertake to guide a plough who could not make one; and that the driver should be able to make of twisted willows the harness with which it was drawn. But simple as these ploughs were, it was usual for six or eight persons to form themselves into a Society for fitting out one of them and providing it with oxen. This is a sufficient proof both of the poverty of the class of men who occupied land, and of the very imperfect state of Agriculture among the Britons at the period in question. If any person laid dung upon a field, he was allowed by law and the consent of the proprietor, to use it for one year; and if the dung was conveyed thither on a cart and in a certain quantity, he was allowed the use of the field for three years. If any man folded his cattle for a whole year upon a piece of ground belonging to another, with his consent, he was allowed to cultivate that ground for his own benefit during the space of four years. All these laws were evidently meant for the encouragement of Agriculture, by increasing the quantity and improving the quality of the arable lands.*

Despised at first by the Anglo-Saxons.

As the Anglo-Saxons derived their origin and manners from the ancient Germans, who depended for subsistence chiefly on their flocks and herds, it may be inferred that they were not much addicted to Agriculture. On the contrary, these haughty warriors esteemed the cultivation of the land too ignoble an employment for themselves, and therefore committed it wholly to their women and slaves. The Chiefs were even at pains to contrive laws to prevent their followers from contracting a taste for Agriculture, lest it should render them less fond of arms and of warlike expeditions. Hence we may conclude that the Anglo-Saxons at the time of their arrival in Britain, were much better warriors than husbandmen; and we find, accordingly, that for a considerable period after they completed their settlement, their attention was almost exclusively confined to deeds of arms. It was not until they had no longer any enemies to plunder, that they found it necessary to devote some portion of their cares to the improvement of the land, in order to raise those provisions which it was no longer possible to procure by the edge of their swords.

Division of Lands.

Rents

in produce,

In the division of the Country, those of the leaders who obtained the largest shares are said to have subdivided their estates into two parts, which were called the *inlands* and the *outlands*. The inlands were those which lay contiguous to the mansion of their owner, which he kept in his own immediate possession, and cultivated by his slaves for the purpose of supplying provisions to his family. The outlands were such as lay at a greater distance from the dwelling of the lord, and were let to the ceorls or farmers at a moderate rent, which was generally paid in kind. The owners of land were not permitted to exact as high a rent from their tenants as they might have obtained by throwing open their lands to competition; the several payments being fixed by law, according to the number of hides or plough-lands of which a farm consisted. The reason of this seems to have been that the first ceorls among the Anglo-Saxons were freemen and soldiers, who had contributed by their arms to the conquest of the Country, and who were therefore entitled to the indulgence just mentioned. By the Laws of Ina, King of the West Saxons, who flourished at the beginning of the VIIIth Century, a farm consisting of ten hides or plough-lands was to pay the following rent, namely, ten casks of honey; three hundred loaves of bread; twelve casks of strong ale; thirty casks of small ale; two oxen; ten wethers; ten geese; twenty hens; ten cheeses; one cask of butter; five salmon; twenty loads of forage; and one hundred eels.* In some places these rents were paid in wheat, rye, oats, malt, flour, hogs, sheep, according to the nature of the farm or the custom of the country.†

in money

There is, however, sufficient evidence that money-rents were not altogether unknown in England, at this period, although the other system prevailed much more extensively. For instance, the greater part of the Crown-lands was farmed in that manner by ceorls, who paid a certain quantity of provisions for the support of the King's household, according to the nature of the grounds which they occupied. "We have been informed," says the author of the *Liber Niger Scaccarii*, "that in ancient times our Kings received neither gold nor silver from their tenants, but only daily provision for the use of their household; the officers who were appointed to manage the King's lands knew very well what quantities and what kinds of provisions every tenant was obliged to pay. This custom continued even after the Conquest, during the whole reign of William I.; and I myself have conversed with several old people who had seen the Royal tenants paying their rents in several kinds of provisions at the King's Court."*

Prices evince great deterioration of Agriculture.

In the ancient *History of the Church of Ely*, published by Dr. Gale, the curious reader will find an account of several purchases of land which were made by Æthelwold, the founder of that church, and by other pious benefactors, in the reign of Edgar, surnamed the Peaceable. By comparing these documents it plainly appears that the ordinary price of an acre of the best land in that part of England, in the Xth Century, was sixteen Saxon pennies, or about four shillings of our money; a very trifling sum indeed, not only in comparison with the prices of land in our times, but even in comparison with the prices of other commodities at the same period. The insecurity of territorial possessions in that rude Age, not only depressed its value; it also necessarily led to the neglect of all the proper means for increasing its produce. The frequent famines which afflicted England, and carried off multitudes of the inhabitants in those days, afford a further and more melancholy proof of the wretched state of cultivation. In particular, there was so great a scarcity of grain in the year 1043, that a quarter of wheat sold for sixty Saxon pennies, which contained as much silver as fifteen of our shillings, and were equal to eight or nine pounds of our present currency; a most extravagant price, which must have involved not only the poor but even those in the middle ranks of life in extreme distress. In a word, we have sufficient evidence that England, which in the time of the Romans was one of the principal granaries of Europe, was so ill cultivated by the Anglo Saxons, that, in the most favourable seasons, it yielded only a scanty provision for its own inhabitants, while, in less propitious years, it presented a scene of the most deplorable scarcity and suffering.†

Rudeness of implements.

Superior husbandry in Church lands.

When such was the state of Agriculture, we may rest assured that the implements by means of which it was carried on were extremely rude and imperfect. The Saxon husbandmen performed, indeed, the processes of ploughing, sowing, and harrowing; but as all these operations were intrusted to slaves who had little interest in their success, they were executed in a very slovenly and superficial manner. Their ploughs were very slight, and, like those of Shetland at a recent period, had but one stilt or handle. Although water-mills for grinding corn were well known to the Visigoths in Spain, and to the Lombards in Italy, the Anglo-Saxons appear to have been unacquainted with them during the period now under consideration, and had no better way of converting their corn into meal than by grinding it in hand-mills, which were turned by women. By the Laws of Ethelbert, King of Kent, a severe fine was imposed upon any man who should debauch the King's grinding maid. The lands belonging to the Monasteries were by far the best cultivated, because the Secular Canons who possessed them spent some part of their time in improving the soil and tending the progress of their crops. Bede, in his life of Eastawin, the Superior of Wearmouth, tells us that this Abbot, being a strong man and of a humble disposition, used to assist his Monks in their rural labours, "sometimes guiding the plough, sometimes winnowing corn, and sometimes forming instruments of husbandry with a hammer on an anvil."[*]

Improvement under the Normans.

Things were greatly improved in relation to Agriculture under the Kings of the Norman race. Immediately after the Conquest, many thousand husbandmen from the fertile plains of Flanders and Normandy settled in this Island, obtained estates or farms, and employed the same methods in the cultivation of them which had proved so successful in their native Country. The Clergy, too, and especially the Monks, rivalled the Nobility in the art of improving the soil. It was in fact so much the custom for the Regulars of this period to assist in the labours of the field, especially in seed-time, the hay-season, and harvest, that the famous à Becket, even after he was Archbishop of Canterbury, used to sally out with the inmates of the Convents near which he happened to reside, and take part with them in all the rural occupations of Spring, Summer, and Autumn. The XXIXth Canon of the General Council of Lateran, held in 1179, affords a further proof that the protection and encouragement of all concerned in Agriculture were objects of attention to the Church. It is thereby decreed, that "all presbyters, clerks, monks, converts, pilgrims, and peasants, when they are engaged in the labours of husbandry, shall, together with the cattle in their ploughs, and the seed which they carry into the field, enjoy perfect security; and that all who molest or interrupt them, if they do not desist when they have been admonished, shall be excommunicated."[†]

Similarity of implements

The implements of husbandry were of the same kind, in this period, with those which are employed at present, though some of them were much less perfect in their construction. The plough, for example, had but one handle or stilt, as it is called, which the ploughman guided with one hand, while in the other he held an instrument both for cleaning the share and breaking the clods. The Norman plough had two wheels, and in the light soil, for which it was constructed, was commonly drawn by one or at most two oxen; but in England, as the land is generally more heavy and tenacious, a greater number of cattle was necessary. Their carts, harrows, scythes, sickles, and flails appear, from the figures of them still remaining, to have been nearly of the same form as those which are now used.[‡]

and of processes to those in modern use.

Although the various processes of husbandry are incidentally mentioned by the Writers of that period, it is nevertheless very difficult to collect from them a distinct account of the manner in which these operations were performed. Marl seems to have been the chief manure in the absence of dung. Summer fallowing of lands designed for wheat appears to have already become a common practice of the Anglo-Norman farmers; for Giraldus Cambrensis, in his description of Wales, takes notice of it as a great singularity in the husbandmen of that Country, "that they ploughed their lands only once a year, in March or April, in order to sow them with oats; but did not like other farmers plough them twice in the Summer and once in Winter, in order to prepare them for wheat." In Mr. Strutt's very curious and valuable Work, we see the figures of several persons engaged in mowing, reaping, threshing, and winnowing; in all which operations there appears to be little that is singular or at all different from modern practice.

Backwardness of Agriculture in Scotland.

The state of Agriculture in Scotland at the same period must have been very imperfect; for in a Parliament held at Scone by Alexander II., in the year 1214, it was enacted that such farmers as had four oxen or cows or upwards, should labour their lands by tilling them with a plough, and should begin to till fifteen days before Candlemas; and that such farmers as had not so many as four oxen, as they could not labour their lands by tilling, should delve so much with hand and foot as would produce a sufficient quantity of corn to supply themselves and their families. But this law was probably meant for the Highlands and most uncultivated parts of the Kingdom; for, in the same Parliament, a very severe law was made against those farmers who did not extirpate a pernicious weed called *guilde* out of their lands; a regulation which seems to indicate a more advanced state of rural economy.

Progress till the XVth Century.

The next three Centuries present such an alternation of high and low prices, of famines and of excessive plentifulness, that we cannot arrive at any just conclusion as to the ordinary state of Agriculture. But there is reason to believe that, although the progress was slow and frequently interrupted by war and domestic broils, there was, on the whole, a considerable advancement. The importance of having the fields enclosed had been very generally admitted. Even "the feeding lands," says Sir John Fortescue, "are likewise surrounded with hedgerows and ditches, planted with trees, which protect the flocks and herds from bleak winds, and sultry heats."[*] Summer-fallowing for wheat was practised in the XIIIth Century as much if not more than it is at present. It was then a kind of rule among farmers to have one-third of their arable lands in fallow. In the law book called *Fleta*, composed in the reign of Edward I., very particular directions are given as to the most proper time and best manner of ploughing and dressing fallows. The farmer is there instructed to plough no deeper in Summer than is necessary for destroying the weeds; not to lay on his manure till a little before the last ploughing, which is to be done with a deep and narrow furrow. Rules are also given for changing and choosing seed; for proportioning the quantity of different kinds to be sown on an acre, according to the nature of the soil and the degree of richness; for collecting and compounding manures, and accommodating them to the ground on which they are to be laid; for determining the particular times in the course of the year best suited for sowing the several descriptions of grain; and, in a word, for performing every operation in husbandry, at the best time and in the best manner. In the same Treatise the duties of the steward, of the bailiff, and of the overseer of a manor, and of all the other persons concerned in the cultivation of it, are explained at full length, and with so much good sense that, if they were well performed, the manor could not be ill cultivated.[†]

Distractions during the latter half of that period.

From the middle of the XIVth till towards the end of the XVth Century, the unsettled state of the kingdom was extremely unfavourable to the interests of Agriculture. The unhappy rustics were not permitted to pursue their toils in peace, but were liable every moment to be called from the plough into the field of battle, by a Royal Proclamation or by the mandates of their own arbitrary lords. Such multitudes of this most useful order of men actually fell in the course of war, that hands were wanting for the necessary operations of husbandry; a circumstance which led, by very natural steps, to the high price of labour characteristic of the period now under consideration. Many laws were made to reduce wages, to compel persons to assist in the cultivation of the land, and to restrain them from following other occupations. In one of these Statutes it is said that Noblemen and others were greatly distressed for want of farm servants; and therefore it was enacted that "whoever had been employed at the plough or cart, or any other husbandry work, till he was twelve years of age, should be compelled to continue in that employment during life; and that none who had not lands or rents of the value of twenty shillings a year, should be permitted to put any of their sons apprentices to any other trade, but should bring them all up to husbandry."*

Extension of pastures.

These severe laws, while they prove the existence of the evil, are known to have supplied a very inadequate remedy. The scarcity of labourers still continued, and even increased to so great a degree as to produce a considerable change in the application and value of landed property. The Barons, Prelates, and other extensive owners kept large tracts round their castles, called their demesnes, which were cultivated either by their villains, or by hired servants under the direction of bailiffs. But these landholders having diminished the number of their retainers by a succession of wars, and not being able to obtain the assistance of Agricultural labour on reasonable terms, resolved to enclose their lands and convert them into pasture-grounds. This practice became very general about the end of the XIVth Century, and occasioned very loud clamour on the part of those who mistook the effect of depopulation for its cause.

Invectives against enclosures.

John Rous of Warwick was a most violent declaimer against the Nobility and Gentry who enclosed their lands; and a considerable part of his *History of England* consists of the most bitter invectives against them on that account. He calls them depopulators, destroyers of villages, robbers, tyrants, basilisks, enemies to God and man; assuring them at the same time that they would all go to the devil when they died. This zealous opposer of abuses tells us that he presented a petition against them to the Parliament which met at Coventry in the year 1459, without obtaining a favourable hearing, and that several petitions to succeeding Parliaments were equally unsuccessful. But although this innovation in the manner of using land was introduced at first by the scarcity of labourers, it cannot be denied that the humour of enclosing arable lands for pasture was at length carried much too far; and we find, accordingly, that Parliament, at a somewhat later period, deemed it expedient to interpose its authority for the purpose of checking the progress of an evil which threatened the most alarming consequences.†

First restrictive corn-law.
A. D. 1463.

It is remarkable that at the epoch in question, although corn was sometimes very dear, it was also occasionally very cheap. In 1455, wheat was sold in certain places so low as one shilling the quarter. But this cheapness, it has been asserted, was not so much owing to any improvements in husbandry, as to an extraordinary importation of wheat from the Continent in order to procure a supply of English wool. To prevent such excessive influxes, which threatened the ruin of the farmer and excited the most violent complaints, a law was passed, in the year 1463, by which it was provided that no grain of any kind should be imported when wheat was below 6*s*. 8*d*., rye under 4*s*., and barley under 3*s*. the quarter. These were then considered such high prices as to call for a supply from foreign parts.*

Continued decline of Agriculture in England,

But the great decrease in the value of land at this period is the strongest proof of the decline of Agriculture. In the reign of Edward III., there are some examples of land being sold at twenty-five years' purchase, which, it is probable, was not much above the common price; whereas in the time of Edward IV., there is the fullest evidence that land had fallen to a value of less than one half. And if Agriculture declined in England in those days, it was still more neglected in Scotland, as the latter Country suffered even more, in proportion to its wealth and population, by long and ruinous wars. The low state of this important Art is manifest from the laws which were made for its improvement. By one of these, passed in 1424, it is enacted that, "ilk man of simple estate, that sould be of ressoun labourers, have either half an ox in the pleuh, or else delve ilk day vii fute of length and vii on breadth." Another law, in 1457, is thus expressed: "Anent the sawing of quheit, peis, and beinis, it is sene speidful, that ilk man wend with a pleug of viii oxen, shall saw at the least ilk year, ane firlot of quheit, half a firlot of peis, and forty beins, under the pane of x shillings to the barenne of that land that he dwells in. And gif the barenne saws not the said corn in his domainis, he shall pay to the King x shillings."†

in Scotland.

The Peace which followed the union of the Roses under the family of Tudor was favourable to many of the Arts, and laid the foundations of that improvement which has advanced with little interruption until the present day. But Agriculture did not share in the general benefit. The practice of converting arable land into pasture still continued during the reign of Henry VII. Enclosures were multiplied, demesne lands were extended, till the farms of most of the husbandmen were appropriated to the feeding of sheep; the houses were demolished or allowed to fall into ruins, while a few shepherds supplanted the yeomen, and occupied in some Counties the largest estates with their increasing flocks.

False policy of exclusive encouragement of the wool trade.

But the cause most detrimental to Agriculture may be discovered in the restrictions attending the exportation of grain, and the large demand for English wool on the Continent. At a former period the exportation of corn had in certain circumstances been permitted, and its importation regulated by different Statutes; but by these restrictions a discretionary power to dispense with their main provisions was committed to the King, and there is reason to believe that the prerogative was seldom exerted unless for the encouragement of private monopolies, or for giving strength to pernicious restraints. It is true that a law was passed at an early stage of this Monarch's government, for the future support of those houses of husbandry to which, within three years, twenty acres of land had been annexed, and enforced by a penalty of half the rent until the grounds should be again occupied and the dwellings rebuilt. But it was not until it become more profitable to raise corn than to feed sheep, that the plains of England were restored once more to tillage. The immense flocks of twenty thousand and upwards, which by a Statute of Henry VIII. were pronounced illegal, gradually gave way before the dominion of the plough, so soon as the manufacturers of the Netherlands were compelled or induced to remove their establishments to Britain.*

Sir A. Fitzherbert's *Book of Husbandry* A. D. 1532.

The reign of Henry VIII. is distinguished for the first native Work on Agriculture published in England. We allude to the *Book of Husbandry*, written by Sir A. Fitzherbert, one of the Judges of the Common Pleas, and highly esteemed even at the present day, as well for the judicious observations which it contains, as for the liberal spirit with which it is animated. He recommends draining, clearing, and enclosing a farm, and gives many good directions for enriching the soil. Lime, marl, and fallowing are strongly urged. The landlords are advised to grant leases to those farmers who will engage to surround their farms and divide them by hedges into proper enclosures; by which operation, he says, "if an acre of land be worth sixpence before it is enclosed, it will be worth eightpence when it is enclosed, by reason of the compost and dunging of the cattle." From the appearance of this book the revival of rural industry in England may be dated. Fitzherbert's remarks on live stock are excellent, and said to be entirely applicable to the business of grazing in our own times. "An housbande can not well thrive by his corne without he have other cattell, nor by his cattell without corne. And bycause that shepe in myne opynyon is the mooste profytablest cattell that any man can have, therefore I purpose to speake fyrst of shepe." After recording various precepts for "quycksittinge, dychinge, and hedgeying," and "for a yonge gentleman that intendeth to thrive," he gives a "prolonge for the wyves occupation." "She must first make herself and himself somme clothes; and she may have the lockes of the shepe eyther to make blanketts and courlettes or bothe." "It is a wyves occupation to winnowe all maner of cornes, to make malte, to washe and wrynge, to make heye, shere corne, and in time of nede to help her husbande to fill the mucke wayne or dounge cart, dryve the ploughe, to loode heye, corne and such other; and to go or ryde to the market to sell butter, chese, mylke, egges, chekyns, capons, hennes, pygges, gese, and all maner of cornes."

produces a revival.

His Book of Surveying. A. D. 1539.

This Treatise was followed by another entitled *Of the Surveying of Lands*, which has likewise added considerably to our knowledge of rural affairs at that period. He takes occasion to mention the different kinds of commons that were then recognised; describes the sundry species of mills which were used for grinding corn, including also the "quernes that go with the hand;" delineates the various orders of tenants down to bondmen, who in some parts of the Country were not yet extinct; and he concludes his Treatise with an inquiry how to make a township that is worth twenty marks a year worth twenty pounds. His views may be learned from the following extract.

"It is undoubted that to every townshyppe that standeth in tillage in the playne country, there be errable lands to plowe and sowe, and leyse to tye or tedder theyr horses and mares upon, and common pasture to kepe and pasture theyr catell, beestes, and shepe upon; and also they have medowe grounde to get theyr hey upon. Than to let it be knone how many acres of errable lande every man hath in tyllage, and of the same acres in every felde to chaunge with his neyghbours, and to leye them toguyther, and to make hym one severall close in every feld for his errable lands; and his leyse in every felde to laye them togyther in one felde, and to make one several close for them all. And also another severall close for his portion of his common pasture, and also his portion of his medowe in a several close by itselfe, and all kept in severall bothe in wynter and somer; and every cottager shall have his portion assigned hym accordynge to his rente, and then shall nat the ryche man overpresse the poore man with his cattell; and every man may eate his owne close at his pleasure. And undoubted, that heye and strawe that will fynd one beeste in the house will find two beestes in the close, and better they shall lyke. For those beestes in the house have short heare and thynne, and towards March they will pylle and be bare; and therefore they may nat abyde in the fylde before the heerdmen in wynter tyme for colde. And those that lye in a close under a heydge have longe heare and thyck, and they will never pylle nor be bare; and by this reason the husbande may kepe twyse as many catell as he did before.

"This is the cause of this approvment. Nowe every husbande hath six severall closes, whereof iii be for corne, the fourthe for his leyse, the fifthe for his commen pastures, and the sixte for his heye; and in wynter tyme there is but one occupied with corne, and than hath the husbande other fyve to occupy till Lente come, and that he hath his fallowe felde, his leye felde, and his pasture felde all sommer. And when he hathe mowen his medowe, than he hath his medowe grounde, soo that if he hath any weyke catell that wold be amended, or dyvers maner of catell, he may put them in any close he wyll, the whych is a grete advantage; and if all shulde lye common, than wolde the edyche of the corne feldes, and the undermath of all the medowes be eaten in x or xii dayes. And the ryche man that hath moche catell wold have the advantage, and the poore man can have no helpe nor relefe in wynter when he hath moste nede; and if an acre of lande be worthe sixe pens, or it be enclosed, it will be worth viii pens whan it is enclosed, by reason of the compostying and dongying of the catell that shall go and lye upon it bothe daye and nyghte; and if any of his thre closes that he hath for his corne be worne or ware bare, than he may brake and plowe up his close that he had for his leyse, or the close that he had for his commen pasture, or bothe, and sowe them with corne, and let the other leye for a tyme, and so shall he have always reish grounde, the whych wyll beare moche corne with lytel donge; and also he shall have a grate profyte of the wod in the heydges whan it is growen; and not only these profytes and advantages before said, but he shall save moche more than all these, for by reason of these closes he shall save mete, drinke, and wages of a shepeheerde, the wages of the heerdman, and the wages of the swineherde, the whych may fortune to be as chargeable as all his holle rent; and also his corne shall be better saved from eatinge or destroyinge with catell. For doubt ye nat but heerdmen with their catell, shepeherdes with their shepe, and tieng of horses and mares, destroyeth moche corne, the which the heydges wold saue. Peradventure some men wold say that this shuld be againste the commen weale, because the shepeherdes, heerdmen, and swyneherdes shuld then be put out of wages. To that it may be answered, though these occupations be not used, there be as many new occupations that were not used before; as getting of quicksettes, dyching, heydging, and plashing, the whych the same men may use and occupy."

---

* Henry, vol. xii. p. 258.

Tusser.

Googe.

Sir Hugh Platt.

Sir R. Weston.

It will be enough to mention the *Five Hundred Points of Husbandry*, by Tusser, published in the year 1562; the *Whole Art of Husbandry*, by Googe, which appeared about sixteen years later; the *Jewell House of Art and Nature*, by Sir Hugh Platt, and several other performances of a similar nature, the object of which was to enlighten the farmers of the XVIth Century. But the attention of the reader ought to be more particularly drawn to a Treatise by Sir Richard Weston, on the *Husbandry of Brabant and Flanders*, for in it may be detected the seeds of the numerous improvements which have since been effected in this Country. Western was Ambassador from England to the Elector Palatine and King of Bohemia; and during his residence on the Continent he became acquainted with the use of clover and probably also of turnips, as a valuable species of food for cattle. His directions for the cultivation of the former, though objectionable in some points, are yet so good as to prove that they must have been derived from experience. It thrives best, he alleges, "when you sow it on the worst and barrenest ground, such as the worst of our heath-land here in England. The ground is to be pared and burnt, and unslacked lime must be added to the ashes. It is next to be well ploughed and harrowed, and about ten pounds of clover seed must be sown upon an acre, in April or the end of March. If you intend to preserve seed, then the second crop must be let stand till it come to a full and dead ripeness; and you shall have at the least five bushels per acre. Being once sown it will last five years; and then, being ploughed, it will yield two or three years together, rich crops of wheat, and after that a crop of grass, with which clover seed is to be sown again."

To Blythe, who published in the time of the Commonwealth, is due the first hint of a rotation in crops, or at least of the advantage which may be derived from alternating clover and turnip with corn on the same field. All the manures now in use were well known in his days, especially lime, on which he set a great value as an ingredient of fertility. A great improvement had likewise taken place in the implements of husbandry. A machine is mentioned which ploughed, harrowed, and sowed at the same time. The following note will amuse the curious reader. "It is not many years since the famous city of London petitioned the Parliament of England against two nuisances or offensive commodities which were likely to come into great use and esteem; and that was Newcastle coal in regard of their stench, and hops in regard they would spoyle the taste of drink and endanger the people."

Evelyn.

Jethro Tull.

The names of Hartlib, Markham, Mascall, Ray, and Evelyn are familiar to every reader on Agriculture, or on rural economy at large. The *Sylva* and *Terra*, of the last of these authors, still retain a merited reputation. In fact, the improvement which took place in the management of land in this Country, from the reign of James II. down to the middle of the last Century, was not very great; and hence the writers on husbandry between the period of the Revolution and the accession of George III. are not, generally speaking, superior to those who published nearly a hundred years before them. The chief exception to this remark applies to Jethro Tull, a gentleman of Berkshire, who introduced the practice of drilling wheat and other crops, about the year 1701, and who, thirty years afterwards, put forth a book on *Horse-hoeing Husbandry*. From an unhappy tone in his manner of writing, as well as from an undue degree of opposition to the usages of his day, his Work made less impression than it ought to have produced in an Agricultural Country. Hence it was not until 1780 that the present method of drilling and horse-hoeing turnips was admitted into Northumberland; at which time it was borrowed from Scotland, where the farmers had the merit of first adopting Tull's management of this valuable root, and whence it made its way but slowly into the more Southern parts of the Island.

Agriculture of Scotland

Improved under the Protectorate.

Declines after the Restoration

Gradually improved since 1745.

In regard to the Agriculture of North Britain, it has been suspected that the accession of James I to the English Crown was unpropitious to it in the first instance, not only because many of the Nobility followed their Sovereign, and were thereby led to neglect their native soil, but also because the increased expenditure of the landlords in a more wealthy Country give rise to various exactions on the poor tenants. The residence of Cromwell's army, however, Northward of the Tweed, during several years of the Protectorate, did more than counterbalance the evils arising from the absence of a Court. The soldiers, being chiefly English yeomen, were necessarily well acquainted with the practice of husbandry; and, like the Romans of old, they showed themselves ready to enlighten the people whom they had subdued. Hence it has been remarked that the low country districts were, at the eve of the Restoration, in a higher state of improvement than they had attained since the death of Alexander III. In the Counties of Lanark, Renfrew, Ayr, and Kirkcudbright, the rents of various estates were higher than they were seventy years afterwards; a fact which may be accounted for by a reference to the disturbed condition of the Kingdom under the last two Monarchs of the Stuart dynasty. A succession of bad seasons immediately after the Revolution, increased the distress of the Scottish farmer, which was still further aggravated by the insurrections of 1715 and 1745. After the last of these attempts to restore the exiled family had exhausted the zeal and means of the Jacobites, the Government of the Country was consolidated, and the sources of her improvement again opened up. Since that period the husbandry of Scotland has advanced regularly and steadily, so as now to bear comparison, local circumstances considered, with that of any Nation in Europe. Since the year 1789 in particular, when the contest with our American Colonies was terminated, the interests of Agriculture have been promoted with astonishing success; and while the rent-rolls of proprietors have been doubled, tripled, and even quadrupled, the condition of the tenants and of the peasantry in general has been meliorated in a corresponding degree.

Agricultural Associations

We believe the first Association for the improvement of rural affairs was formed in Scotland in the year 1723; at which time a number of landholders constituted themselves into a Body, under the title of the *Society of Improvers in the Knowledge of Agriculture.* The *Select Transactions* of this fraternity were published in 1743, and exhibit an accurate acquaintance with the best modes of conducting the various processes of farming at that time pursued in the most enlightened parts of Europe. This example was followed, at a more recent date, by the *Bath and West of England Society*, and by the *Highland Society* of Scotland. The *National Board of Agriculture* derived its origin from similar views: but as such Institutions are usually better conducted by the voluntary labours of individuals than by the official Members of Government, the Crown has for some time withdrawn its patronage. The same object is perhaps equally well accomplished by the general circulation of knowledge through the medium of the Press. The numerous *Farmers' Magazines* and *Agricultural Journals*, while they attest the interest which is taken in this important pursuit, make known over the whole Empire the result of every experiment; for, it is worthy of remark that, in this branch of industry, there are neither secrets nor privileged discoverers; every one communicating to another whatever new views accident or research may have brought to light.

and publications.

Recent state of Agriculture on the Continent of Europe.

We shall conclude this Historical sketch with an extract from a communication to the *Quarterly Journal of Agriculture*, relative to the recent condition of husbandry on the Continent of Europe. The author, Mr. Boswell, had just finished an extensive tour in France, Holland, Swisserland, Italy, and Spain, and as he appears to possess a practical knowledge of the subject on which he writes, his remarks are not without considerable value. "That the Agriculture of Britain," says he, "is superior to that of the Continent, or indeed, of the whole World, every one must admit who knows any thing of the matter; but to explain the causes of this superiority may not be a matter of so easy discovery. Our climate, at least in Scotland, is bad; our soil is by no means uniformly fertile, and there are other causes which at first sight seem to put a *veto* on improvement in the Art of Agriculture; yet with all these disadvantages to contend against, it cannot be denied that we have risen superior to all the World. Of course I make this broad assertion on the authority of those who have visited the other quarters of the Globe. For my own part, it has been my lot to see a considerable part of Southern Europe, and comparatively speaking I am safe in saying that I have never yet seen a well-drawn furrow or drill by a foreigner. I make use of the word foreigner, because in visiting Xeres de la Fronteira, in the Winter of 1809, I was shown a very beautiful crop of turnips with drills drawn in the most masterly style; but these were found on inquiry to have been made by East Lothian ploughmen, brought to the Peninsula by my kind host Mr. Gordon, whose exertions for the improvement of that part of Spain were neither known nor rightly appreciated by that stupid and tyrannical Government. In making this statement some may set me down as one of those prejudiced people who in a John Bull sort of way will not allow any merit to exist out of this little Island. But I wish it to be clearly understood that my remark is intended to apply only to the department of Agriculture, or rather to the operations of the ploughman, for I have frequently seen more beautiful specimens of spade culture abroad than in our own Country: this, however, more properly belongs to Horticulture. On the Continent their implements are so defective that it is impossible the work can be well performed; hence, wherever there is a dense population, and the *petite culture*, as the French call it, is followed, there one commonly finds spade-work exceedingly well done, particularly where the vine is cultivated: but the moment they farm on a large scale it is execrable. I scarcely know where to say that the Agriculture is the worst. It seems to be in an inverse ratio of the goodness of the climate and fertility of the soil, that the farming is bad. In the States of the Pope, where the soil and climate cannot be excelled, I think I may say it is the worst. In all my wanderings, with one solitary exception, at Kofwyil near Berne, I may truly say I have never seen a plough! A clumsy thing made of a few pieces of bent wood, fastened together with one or two hobnails, is used for tilling, and although this implement varies in form in different Countries, it is every where equally remote from the plough of this Country, constructed in the manner which Science points out to be the best. With such a tool as I have described to stir the soil, it is almost superfluous to say that the work more resembles the pastime of a herd-boy, or pigs hunting for truffles, than the work of a Norfolk or a Scotch ploughman. Over a great part of the Continent, the harrow is an implement not even known. In some parts of Flanders, on the Rhine, in Prussia, and Germany, they use what they call a harrow, a small triangular frame of wood into which are inserted a few wooden pins. Wretched, however, as it would be esteemed by our farmers, it is a refinement in Agriculture not known on the fertile plains of Spain or France, on the wide-extending Campagna di Roma, or in the farming of Calabria, where they either plough down the seed, or not unfrequently cover it by throwing earth upon it with an implement in form between a hoe and a spade, leaving the ground, when the operation is finished, in long beds, such as those in which the gardeners grow onions.

"The best farming on the large scale which I have seen is in Flanders, near Waterloo, and in the adjoining part of the Country; but it is clumsy, and performed with very defective instruments. In Tuscany the soil is by far the best cultivated; but it is generally speaking in small holdings, and the greatest part is done by manual labour; although they also use the plough a good deal, making the oxen work close to the rows of vines, which border every field, and which they are prevented from eating by a slight muzzle of basket-work hung in their noses. The Tuscan plough is not nearly so rude as that made use of in many other Countries; and the Tuscan Agriculturists are even acquainted with our method of opening drills, putting in manure, and then closing them with the plough. Taking you Northward by a very rapid journey from this part of Italy to Berne, I shall say a few words respecting Hofwyil. Here the British Agriculturist, who visits the farm of M. Fellenberg, is surprised to find not only all the newest and best improvements in Agricultural implements, as used in Great Britain, but many invented by himself, and constructed at Hofwyil, which surpass in simplicity and beauty the best I have seen at Holkham. I was particularly pleased with a corn-driller, which had a dial and index to show the ground gone over; thus possessing the double advantage of showing the work done by the horses, and the quantity of seed used per acre. This farm is like the most beautiful garden as to neatness, and being free from weeds. All that is done by the spade and hoe is capital, there can be no better work. But if I, who was well acquainted with the farming of East Lothian, felt the greatest surprise on first seeing the correctness, I might say the mathematical precision of the drill-husbandry of Holkham, what would be the feelings of M. Fellenberg, if he could see and compare that *ne plus ultra* of good workmanship with the bungling performance of his own people, provided as they are with such admirable tools to work with?

"There is one feature in the Agriculture of the Continent which ought to be adverted to. In this Country, when we read an account of any other part of the World, and are told that it is all enclosed, we naturally imagine to ourselves cattle feeding quietly, or corn growing in separate fields. But how sadly disappointed is the British traveller to discover the mistake into which he has been led, and to find that the enclosures, where there are any, have been formed, not to keep in, but to keep out cattle. If one of our Countrymen land in Holland, and behold the beautiful meadows full of the finest cattle, he is led to think that things are not very different from what he has been accustomed to at home. But he must very soon change his opinions, for he quickly gets into a Country where there is nothing but the soiling system known or used; and if he proceed Southward he will not see another animal in a field, till, after a journey of hundreds of miles, he reach the Pontine Marshes between Rome and Naples. In some places, indeed, they drive them out in the daytime to pick a few weeds in the lanes, or on the outsides of the enclosures, which are generally a ditch and a bank of earth, made very deep, and smoothed with the back of a spade when the mud is wet; and in some mountainous districts, such as the Tyrol, one sees herds browsing on the sides of the steeps, but it is generally at such a distance that, except to fill up the beauty of the landscape, the sight of them is no way useful to the inquiring Agriculturist. Sometimes, late in the evening or very early in the morning, one may, from the window of a village inn, get a passing view of the kine; and most peaceful is the sight, while the varied sound from the bell, or rather canister, which hangs appended to the neck of each, forms most appropriate and pastoral music. But on descending again to the plains, the soiling plan is once more found to be the only one of treating live stock; a method which, however well it may answer as to gaining dung, is certainly bad for the cattle; for I have observed that where the soiling system is followed, they are universally poor-looking, knock-kneed creatures of very small size. In Holland and in the Pontine Marshes, on the contrary, where they feed on the sward, they are very fine.

"On comparing the Agriculture of the Continent with that of this Country, we are indeed struck with the miserable manner in which the operations of the plough and harrow are conducted; but the great deficiency is a total ignorance of what we call green-cropping on the large scale. It is true that both potatoes and turnips are used in the different Countries; but I have never seen them properly cultivated, and, consequently, never approaching to a full crop. In Flanders, Prussia, Germany, and in the Swiss cantons, there is no one who holds land but grows a portion of potatoes: but they are planted either by the hand on a flat surface, or put in with a spade, so close that, instead of horse-hoeing, it is wonderful to me how they can get them hand-hoed; the consequence of which is that the potatoes never reach the size of a common egg. But the measure of bad farming is filled up by the rude method adopted for thrashing out the corn, still making use of cattle or horses, at least in all the Southern parts of Europe, to tread it out as we read in the Scriptures."*

On the Theory of Agriculture.

Customary faults of Agricultural Theories.

Although Husbandry is an Art which has been carried on from the earliest Ages by a greater number of people than are concerned in any other, yet even at this advanced period, the speculative Agriculturist may in some measure be viewed as remaining without any fixed principles on which to found his precepts. Instead of resorting to practice, and thence forming a satisfactory Theory, writers on Agriculture, in numberless instances, have amused themselves without instructing their readers by presenting abstract opinions on this important subject; not reflecting that every kind of Theory which is not built upon extensive experience, is fallacious and sometimes positively absurd. According to the method adopted by these authors, he who argues most ingeniously must necessarily be regarded as coming nearest to the Truth; and his doctrine will, therefore, be considered as the standard until some other shall start up, whose eloquence may prove more persuasive, and whose notions may be held more plausible. This has been the fate of all Philosophical conclusions on this subject, since the earliest times. For example, how numerous and diversified are the sentiments of Theorists respecting the food of plants; although it is a certain fact that the most acute Naturalist can no more account for the germination of a single grain of corn, than he can explain the mysterious grounds on which he himself enjoys a rational existence.* Without, therefore, stopping to inquire whether the gaseous substances, oxygen, hydrogen, in their separate state, or a combination of them in the form of air and water, or the oxides of those metallic bases which give rise to the various earths, constitute the *pabulum* of the vegetable species, it may be remarked that the dullest farmer knows sufficiently that if he drains, cleans, and manures his land in a proper manner, it will yield him as good a crop as the soil is constitutionally capable of producing, provided Physical circumstances, such as heavy rains, excessive droughts, or furious winds do not prevent Nature from discharging her usual functions. As we neither have the command of the essential elements which minister to vegetation, nor can order the Sun to display his beams, nor the atmosphere to afford genial gales, nor the clouds to drop refreshing showers, little benefit could accrue to the operative husbandman were even the curtain of Nature drawn aside, and our eyes permitted to roam at large over a field which may justly be regarded as forbidden to Man. Under these impressions we are inclined to consider all abstruse disquisition, respecting the Chemical properties of Matter, the Physiology of plants, and the structure of their several organs, as rather out of place in a Treatise on Practical Agriculture. Regarded as a Science, indeed, there is no absurdity in connecting it with every other branch of investigation which has the analysis of matter for its object. Nay, in a certain sense it might be made to derive light and assistance from Astronomy, Anatomy, Mechanical Philosophy, and Pharmacy; for the cultivator has to study the seasons, the corporeal qualities of the horse, the composition of forces in the application of its strength, and the effect of drugs in repelling its disease. But it is obvious that similar argument might be used for the necessity of scientific knowledge in all the other departments of human industry, inasmuch as every

---

* Brown on *Rural Affairs*, vol. i. p. 69.

Art that is practised, even by the most ignorant operative, has a dependence more or less remote upon Philosophical Principles. Besides, Agriculture, above all other Arts, is founded on experiment, and has uniformly derived its most important improvements from trials judiciously made and carefully repeated. The man of Science, in this case, only follows and discovers, or endeavours to discover, a reason for the successful result which has been already ascertained; and, by generalizing the truth implied in some particular fact, he perhaps aids the application of it to a greater variety of objects. If there be any branch of Physical research which has a peculiar claim to the attention of the Agriculturist, it may be conceived that this distinction belongs to Chemistry; the means supplied by which are so efficacious for analyzing soils, detecting the qualities of manure, and determining the composition of the vegetable products. But it is well known that very little reliance can be placed on the best-conducted Chemical process for ascertaining the properties of land, or its fitness for particular crops. The eye of an experienced farmer is much more to be relied upon in the selection of a field, than the report of the ablest Lecturer who ever used a test, or presided over a crucible. In many instances it would not be more hopeless to undertake the estimate of a man's temper and talents from the weight of his body or the tint of his complexion, than it is to fix the precise qualities of the several portions of a farm, by subjecting a specimen of the soil to the operation of an acid or an alkali.

Causes of the failure of speculation.

We mean it not to be inferred from these observations that the Principles of Science are inapplicable to the advancement of Agriculture. On the contrary, we are satisfied that every step which is gained by the Philosopher in his acquaintance with the composition and powers of Matter, whether in its solid or gaseous form, will ultimately produce an effect in extending the empire of Man over the elements of Nature, and thereby add to his wealth and comfort. Our remarks have no other object than to establish the important maxim, that the labours of the husbandman are directed by Principles so simple that his success will never be found impeded by his ignorance of the refined disquisitions of the Physiologist or Chemist. For example, were he at a loss to determine the effect of bone-manure, of rape-cake, of nitre, or of kelp on a piece of land, he could not have his doubts resolved by consulting the most learned Work on the Philosophy of Agriculture, because the action of these substances depends entirely on circumstances which cannot be brought under any general description or reduced to one rule. The rape-cake might suit one part of the field, and the nitre might answer better for some other part of it; and yet so far as Chemical analysis could proceed in deciding the question, the soil of the whole would probably be declared homogeneous and fitted for one system of management. The points which give the distinguishing character to a section of arable ground, must in general be sought for under the surface. The subsoil has a great influence in aiding or counteracting the effect of manure, and in requiring a greater or less quantity of labour; perhaps the Geological structure of the surrounding platform interposes an energy which may assist in defeating or promoting the intentions of the cultivator; and the mineral bodies which lurk in its recesses may contribute their share also in covering the face of the country with a plentiful harvest, or in blasting it with sterility. Hence it is universally admitted that no man is so unlikely to prosper as a speculative farmer. The failures which have almost constantly ensued among Scientific projectors, who set at naught the lessons of experience, have created in many parts of the country an undue prejudice against all change, even when it wears the aspect of a manifest improvement. To the same cause must be ascribed the little success which in most cases attends the processes of gentleman-farming; for, besides the greater expense incident to the different style of living among the servants, there is a natural tendency in every educated mind to promote the Arts by the aid of experiment.

Three safest Principles.

The safest Theory of Agriculture, therefore, is that which comprehends those Principles only which have been confirmed by observation and long practice; such, for example, as that the soil should be well drained, or kept free from all superfluous moisture; secondly, that it should be kept clean or free from all noxious weeds; and thirdly, that it should be kept rich, or in other words, that every particle of manure which can be collected ought to be applied, so that it should be retained in a state capable of yielding good crops.

1. Draining.

In the first place, the necessity of preserving the land in a dry state is so obvious, that few arguments will be required in support of this preliminary Principle. When ground is allowed to remain wet, which may be occasioned by springs in the undersoil, or by rain-water stagnating on the surface, the earth becomes sour and thereby extremely unfavourable to the growth of plants; and often in the first instance prevents either ploughing or harrowing from being successfully accomplished. Under such circumstances the young plants, whether of corn or grass, appear yellow and sickly, and never assume that vigorous aspect which they exhibit in fields properly drained. Besides, manure fails to produce its wonted effect when the land is drowned by water from above or from below. In fact, without attention to this essential operation, neither can arable land be perfectly managed, nor can good crops be raised. Perhaps the progress of farming in any particular country may be more correctly estimated by the care bestowed upon drainage than by any other mark whatever.

2. Weeding.

In the second place, the benefit derived from keeping the soil free from weeds is equally beyond dispute. Weeds, it has been remarked, whether annual or perennial, may be regarded as preferable creditors of the land, who will reap the first advantage of manure if allowed to remain in possession; their removal, therefore, forms an important object of the husbandman's attention. Without detailing in this place the most effectual means for effecting that purpose, it may be asserted, that in proportion to the success which follows the use of the means employed, so will the goodness or badness of the crop be determined. If the nutritive powers of a field be exhausted by weeds, or by such plants as the soil naturally produces, it is impossible that the artificial plants can prosper. It rarely happens indeed that the natives are altogether extirpated, even by the most sedulous farmer; but it is true, nevertheless, that upon the smallness of their number depends the amount of the return which the Earth makes to Man for the toil bestowed upon its cultivation.

3. Manuring.

In the third place, the necessity of restoring to the land, in the shape of manure, the fertility or powers of production, drawn from it by a succession of crops, is acknowledged by every one, except the disciples of Jethro Tull, if there be any of that School now remaining. Manure, in fact, is the most powerful agent in the hands of the farmer; and the attention bestowed upon collecting, preparing, and applying, constitutes an important branch of the Art which he practises. Perhaps in the practical details connected with this general Principle, Agriculturists are more deficient than in the duties which respect the two others; and here the advantages of Chemical knowledge will be recognised by many who, on the whole, are not friendly to its more speculative tenets.[*]

Obvious necessity of tillage.

In these fundamental Principles we have omitted the operations of tillage, because the veriest Savage is aware that the surface of the ground must be scratched before the seed is deposited into it. An expert farmer is convinced that before a piece of land can be expected to put forth its strength, it must be well pulverized, and exposed to the action of the sun and air; but as this is one of the processes which must be taken for granted, and belongs rather to the Practice than the Theory of Agriculture, we shall proceed at once to discuss the more important parts of the subject on which we have entered, beginning with a consideration of the different kinds of Soil.

Soil.

Composition and formation.

Soil may be defined to be that layer of loose earthy matter which constitutes the upper covering of the Globe, affords a stratum to the roots of innumerable tribes of vegetables, and supplies them with nourishment to promote their growth and bring them to maturity. It consists of the primitive earths which enter into the composition of the prevailing strata or rocks, from the disintegration of which it is obviously formed. The succeeding layer on which the vegetable Soil reposes, whatever be its nature, whether it be composed of less coherent or of more solid materials, is usually distinguished by the name of undersoil or subsoil. We have said that the upper coating, which ministers to vegetation, is derived from the decomposed ingredients of the rocks or strata on which it rests, or of those in the immediate neighbourhood, the *débris* of which is conveyed by means of water. The formation of Soil is, indeed, a beautiful process carried on by Nature, and is accomplished by the combined influence of moisture and temperature on the rocky girdle of the Earth. The changes which take place in this Physical metamorphosis succeed each other with more or less rapidity, according to the nature of the rocks and the power of the agents which operate in their decomposition. In a warm country and moist climate where vegetation is vigorous, it proceeds with astonishing celerity; but in the colder regions of the Earth it advances with slower and more progressive steps. But whatever may be its progress, the hardest rocks, as well as those of less durable and less coherent materials, are subject to disintegration and decay, contributing, as they dissolve, to the formation and increase of Soil.

Progress.

By observing what is daily taking place around us, it is not difficult to trace at least the first steps of this process, by which in the course of Ages the hills are lowered and the valleys are exalted. A bare rock when it is uncovered, or a mass of stone which has been lately dug from the quarry, when fully exposed to the air, soon loses its fresh appearance and assumes a different aspect. When this change is investigated it is found that the surface of the stone is covered with a thin crust, of a substance very different from the stone itself. A closer inspection shows that this crust is a vegetable production belonging to the tribe of plants known by the name of *lichens*, and supposed, perhaps from ignorance or the want of means to examine them, to be less perfect than other plants. The seeds of course are extremely minute, easily wafted about by the wind, and floating in the atmosphere attach themselves most readily to those bodies which are somewhat moist. Porous rocks, which are most apt to absorb moisture from the Earth or from the Air, are the first on which lichens make their appearance. By means of this vegetable covering, a larger portion of moisture is absorbed, and a smaller portion of what rises through the rocky substance from the Earth is lost by evaporation: this affords additional nourishment and increases the power of vegetation. A thin layer is soon detached from the surface of the rock and reduced to the earthy form. The first vegetable productions, in the change of the seasons, decay; and hence the first thin stratum of Soil is formed by the decomposition of the vegetable matter and the disintegration of part of the mass of stone in which it was produced. Plants of a larger size and more vigorous growth, whose seeds are carried about in the air, find a fit receptacle in this mixed mass for their vegetation and growth. They in their turn decay, and contribute a fresh portion of vegetable substance, while another accession of earthy particles, derived from the stone, is made to the general mass. Insects and worms which make their abode in the earth or in plants, in the progressive changes to which they are subject and in the various stages of their existence, deposit animal remains in the places which they frequent; and these also serve to increase the quantity of organized matter in the new Soil. Tracing the operation of these causes in the production of fertilized earth, we see the manner in which the surface of the ground is prepared for the reception of innumerable species of plants.

How regulated.

Every kind of rock even of the hardest and densest nature is subject to this change. The purest rock crystal when exposed to the weather is deprived, in no long period, of its brilliant lustre and fine polish; but the extent and rapidity of the change, we need not remark, correspond with the nature of the rocky substance and the heat and moisture of the climate. In the warmer regions of the Earth the surface of a bare rock is soon converted into friable earthy matter, covered with verdure and clothed with trees; but in colder climates, as has been already remarked, the process is slower as well as more limited. The vegetables which spring up are of smaller size as well as of more tardy growth, and thus afford a more scanty contribution to the formation of Soil.

Different modifications.

It is obvious from what has been just stated, that the diversity of earthy matters contained in the Soil must depend on the constituent parts of the rocks from which it is derived. Rocks in which the prevailing ingredient is silicious earth, afford a sandy Soil; those rocks, again, in which alumina, or pure clay, predominates, yield a clayey Soil; while calcareous earth abounds in the Soil which is formed of the detrition or decomposition of limestone rocks. But the Soil formed by this process of disintegration and Chemical affinity, does not always remain on the spot where it is at first deposited. On the contrary it is carried by floods from the higher to the lower grounds, where it is gradually lodged, and on which, in a succession of Ages, it forms a thick bed. When the earthy matters are swept away by rivers with a slow current, they are deposited on their flat banks or at wide estuaries. In this way some of the richest Soils have been formed. The fertile lands at the mouth of the Nile, of the Po, of the Thames, and the Forth present examples of this result. Gravelly soil, on the other hand, draws its origin from those rocks whose lofty precipices are exposed to the weather; but especially from such rocks as have many fissures and cavities, and thereby retain water in their bosoms. This water when it is near the surface is frozen in Winter, and by its expansive force when passing into ice, separates and throws down immense fragments. These masses, broken in their fall, are reduced to pieces of still smaller magnitude by the current of rivers, or the agitation of lakes through which they are sometimes carried by the rush of a mountain stream. In the progress of those changes which the face of the Earth every where exhibits, the river changes its course, the sea recedes or advances upon the land, the lake is dried up, and the bank of gravel becomes dry ground. The seeds of vegetables fall on its surface, grow up, and decay; these are succeeded by other generations which run the same course; a portion of earthy matter is obtained from the stones on which the vegetable remains are deposited, and, being mixed with the loose fragments, form at length a Soil which invites the culture of the husbandman.

---

[*] *Brown on Rural Affairs*, vol. i. p. 72.

Effects produced by water.

A moist climate and water stagnating in low grounds have a powerful effect in modifying the Soil. In elevated situations the chilling influence of cold permits only plants of a coarse and hardy character to come to maturity; when they die the same causes prevent or retard their decomposition; and in such places the Soil consists of a mass of half-decayed roots and stems of different species of heath and sedge-grass, with which it is almost entirely occupied. This is the origin of moorish Soils. In places, again, where water lodges permanently, a different race of plants is produced, The bog-moss, or *Sphagnum palustre*, first makes its appearance; a new race of the same species succeeds; other species and plants of a different character find a convenient station in the floating mass; and from the accumulation of innumerable generations of various kinds of vegetables in a state of imperfect decomposition, peaty or mossy Soil derives its origin.

Occasional ingredients of Soil.

Besides the ingredients already mentioned, which may be considered as the base of different Soils, other substances enter into their composition. Some of these (as magnesia, which is sparingly met with in Soils, and contain other metallic substances with which they are impregnated) are understood to have originally existed in the rocks from the disintegration of which the land has been formed. Saline minerals, too, which are sometimes found in cultivated grounds, have the same origin, though they are occasionally deposited by the water of springs as it filtrates through the Soil. The stratum which immediately supports the surface layer in which vegetables grow, is distinguished, as we have said above, by the name of subsoil. It sometimes happens that this undersoil is composed of the rock which furnished the materials for the Soil itself; but it more frequently consists of a bed of gravel, or clay, or sand. A knowledge of the nature of the subsoil is of no small consequence in conducting improvements in Agriculture. It is often the best guide in draining; and in the operation of tillage, when it is within reach of the plough, it may be avoided or partially turned up, as the ingredients of which it is composed when mixed with the Soil are found to be beneficial or otherwise.

Classification.

Hence it appears that Soils may be classed under the several heads of clayey, sandy, gravelly, and peaty or mossy. There is a fifth, which, from its quality, has been denominated loam, and from its history or origin has got the name of alluvial. The principal of these, as we have already suggested, are from the depositions of rivers or of the sea, and are generally rich clays fully impregnated with animal matter in a state of complete solution. Peat, by good management, has sometimes been brought to the condition of loam, and rendered extremely well suited to the culture of what are called the tuberous-rooted plants. It is dark in its colour like the richest vegetable mould, and to the inexperienced eye may pass as such; but still, unless greatly corrected in its texture by the application of the firmer earths, it is found upon trial to be porous and loose, too easily saturated with moisture and too easily freed from it. In this improved state, however, it will yield bulky crops of oats and barley, although the quantity of grain does not always correspond to the weight of the stem or the quantity of the straw.

Uselessness of a more Scientific nomenclature.

The simple nomenclature just given is perfectly intelligible to the practical farmer, although, perhaps, in a Scientific point of view, it might be rendered more complete by adopting the language of the Schools. The clayey, sandy, gravelly, and peaty soils might be termed *genera*, and again divided into *species* and *varieties*. But it is thought better, in the mean time, not to disturb the ordinary speech of the fields and farm-yard. As our knowledge of the composition of Soils increases, we may hope to attain a more scientific nomenclature founded on that knowledge; but nothing of this kind that has yet been attempted can be regarded in the smallest degree as a substitute for the apparently inartificial divisions of the practical husbandman. He chiefly regards Soils with reference to their fertility and the means of cultivating them; and if they are not classed conformably to these views, the arrangement will fail in the main purpose contemplated. Some continental writers of eminence have adopted a very complex system of terms as applicable to the different kinds of land; but they are such as the practical farmer will at once perceive to afford no assistance so far as regards the details of his business. What, for example, should we think of a Soil said to belong to the class *Secondary*; of the order *Earths with organic remains*; of the genus *Coal*; of the species *Pyritic*; of the variety *Black*; and of the sub-variety *Moist?* Such a nomenclature may amuse in the Study, but can direct to no useful practice out of it. Some writers on English Agriculture, more practical than speculative, have, on the other hand, deviated into an error not less perplexing than that now alluded to; for, by an unnecessary mixture of local descriptions and phrases, they have rendered their Works almost unintelligible to those who live beyond the confines of a particular district. They have moreover confounded genera, species, and varieties. Garden-mould, for instance, is given as a distinct division of Soil, in the same sense in which clays, sands, and gravels are said to be so. But garden-mould is merely loam, which, as has been already observed is included in one or other of the classes above-mentioned. Chalk, too, is described as a separate class. But chalk, as every one knows, is the subsoil and not the Soil: and we may assert that in Countries where this formation exists, no Soils are to be met with which may not be comprehended in the divisions already given, accor clay, gravel, or sand predominates in their compo

Occurrence of vegetable and animal matter.

We have said that Soils are principally composed of the comminuted earths, which form the substance of the rocky masses which are observed to encircle the Globe. These are silica, alumina, lime, and magnesia, which are sometimes found in a pure state, but more frequently combined with acids, alkalis, and oxygen, one of the component parts of atmospherical air. Vegetable and animal matter, too, in a state of decomposition, forms an essential ingredient in all good Soils. The former exists in very different states, containing a large proportion of carbonaceous substance, and yielding no volatile alkali. It is the chief ingredient in peats, and is abundant in all rich moulds. The state of animal matter in the Soil is as different as the substances from which it is obtained. It usually contains less carbonaceous matter than vegetable substances; and when exposed to heat, ammonia or volatile alkali, and carbonic acid. It is abundant in Soils to which manure has been lately applied.

---

* *Quarterly Journal of Agriculture* vol. i. p 31

Minuter distinctions.

It is evident, therefore, from what has been said respecting the production of Soils from rocks, that there must be at least as many varieties of Soil as there are species of rocks exposed at the surface of the earth. In fact there are many more. Independently of the changes produced by cultivation and the exertions of human labour, other materials of strata have been mixed together and transported from place to place by various great alterations which have occurred in the system of our Globe, and by the constant operation of water. The term sandy, however, should not be applied to any Soil which does not contain seven-eighths of sand: sandy Soils that effervesce with acids, should be distinguished by the name of *calcareous* sandy Soils, to distinguish them from such as are silicious, and which do not effervesce with acids. The term *clayey* should not be applied to any land which contains less than one-sixth of impalpable earthy matter, not considerably effervescing with acids; while the word *loam* should be restricted to Soils containing at least one-third of impalpable earthy matter copiously effervescing with acids. A Soil to be considered as *peaty*, ought to contain at least one-half of vegetable matter. In cases where the earthy part of a Soil evidently consists of a decomposed matter of one particular rock, a name derived from the rock may with propriety be applied to it. Thus, if a fine red earth be found immediately above decomposing basalt, it may be denominated *basaltic* Soil. If fragments of quartz and mica be found abundant in the materials of the Soil, which is often the case, it may be denominated *granitic* soil; and the same principles may be applied to other like instances.[*]

Varieties of alluvial Soil.

"In general," says Sir H. Davy, "the Soils the materials of which are most various and heterogeneous are those called alluvial, or which have been formed by the depositions of rivers; many of them are extremely fertile. I have examined some productive alluvial Soils which have been very different in their composition. A specimen from the banks of the river Parret in Somersetshire, afforded me eight parts of finely-divided matter, and one part of silicious sand; and an analysis of the former gave the following results:

	Parts.
Carbonate of lime	360
Alumina	25
Silica	20
Oxide of iron	8
Vegetable, animal, and saline matter	19

"A rich Soil from the neighbourhood of the Avon in the valley of Evesham, in Worcestershire, afforded me three-fifths of fine sand, and two-fifths of impalpable matter. This last consisted of

	Parts.
Alumina	35
Silica	41
Carbonate of lime	14
Oxide of iron	3
Vegetable, animal, and saline matter	7

"A specimen of good Soil from Teviotdale afforded five-sixths of fine silicious sand, and one-sixth of impalpable matter; which consisted of

	Parts.
Alumina	41
Silica	42
Carbonate of lime	4
Oxide of iron	5
Vegetable, animal, and saline matter	8

"A Soil yielding excellent pasture from the valley of the Avon near Salisbury, afforded one-eleventh of coarse silicious sand; and the finely-divided matter consisted of

	Parts.
Alumina	7
Silica	14
Carbonate of lime	63
Oxide of iron	2
Vegetable, animal, and saline matter	14"[*]

Knowledge of Soils furnishes useful correctives.

The knowledge acquired by this analytical process of the component parts of Soils, possesses its chief value as it suggests the readiest means for the improvement of bad land, as well as for the successful management of that which is good. In ascertaining the composition of sterile Soils, for instance, any particular ingredient which is the cause of their unproductiveness will probably attract the notice of the Agricultural Chemist; whom in this case, the farmer should employ exactly on the same principle as he calls in the Farrier when his horses are sick, or the Physician when a disease has found its way into his family. If, for example, in analyzing a portion of barren Soil, it be found to contain the salt of iron, or any other acid matter, it may be ameliorated by the application of quick-lime. A Soil of an apparently good texture was put into the hands of Sir H. Davy, as remarkable for sterility. On examining it he found that it contained sulphate of iron, and accordingly recommended the obvious remedy of top-dressing with lime, which converted the sulphate into a manure. If there be an excess of calcareous matter in the Soil, it may be improved by the application of sand or clay. Soils, again, too abundant in sand are benefited by the use of clay or marl or vegetable matter. Peat as a top-dressing has been found to answer well for correcting the defects of a light sandy Soil; while a deficiency of vegetable or animal matter must be supplied by the richest species of manures. An excess of vegetable matter, on the other hand, is to be removed by burning, or to be remedied by the application of earthy materials. The improvement of peats, or bogs, or marsh lands must be preceded by draining; stagnant water being injurious to all the nutritive classes of plants. Soft black peats when drained, are often made productive by the mere application of sand or clay as a top-dressing. When peats are acid, or contain ferruginous salts, calcareous matter is absolutely necessary in bringing them into cultivation.

---

[*] *Agricultural Chemistry*, p. 184.

[*] *Agricultural Chemistry*, p. 186.

When they abound in the branches and roots of trees, or when their surface entirely consists of living vegetables, these must either be removed or destroyed by burning. In the latter case, their ashes afford earthy ingredients fitted to improve the texture of the Soil on which they were formerly an incumbrance. In a word, the best natural Soils are those of which the materials have been derived from different strata of rocks; which have been most minutely divided by air and water, and are intimately blended together; and in improving Soils artificially the farmer cannot do better than imitate the processes of Nature. The materials necessary for the purpose are seldom far distant; coarse sand is often found immediately on chalk; and beds of sand and gravel are common below clay. The labour of improving the texture and constitution of the Soil is repaid by a great permanent advantage, for its fertility is thereby placed on a lasting basis; and while the annual outlay is lessened the yearly produce is increased.

Modes of examining Soils.

In whatever way a Soil is to be examined, specimens of it should be taken from different parts of the field, and a few inches below the surface; and it should be carefully ascertained whether these portions so selected possess similar properties. On extensive plains the whole of the Soil is found to be rather uniform in the nature and proportion of the ingredients of which it is composed; but in valleys and near the beds of rivers which are supplied with the materials of the Soil from the higher grounds, there is necessarily a greater variety. One part of the field presents a calcareous Soil, and another a silicious. The specific gravity in all cases is an indication of the quantity of organized matter which it contains; for such matter is most abundant in lighter Soils. To ascertain the specific gravity of any given layer of earth, an equal bulk of it and of water may be introduced into a phial of a determinate capacity. If a bottle containing four hundred grains of water be half-filled with that liquid, and if the remaining half be filled with the Soil to be examined, and if the bottle gain two hundred grains of weight more than when it is entirely filled with water, the specific gravity of the Soil is double that of the water. The colour, feel, and some other Physical properties of Soils may, to a certain extent, lead to a knowledge of their composition. For example, a silicious Soil is rough and hard to the touch, and when rubbed on glass scratches it. A red or yellow colour denotes a ferruginous Soil, while softness in general denotes one that is calcareous.

Influence of temperature.

The power of absorbing and retaining heat and moisture seems to be closely connected with fertility of Soil. Certain Soils are more easily heated than others, and when brought to the same degree of temperature, cool more rapidly. Stiff white clay is heated with difficulty, and from the quantity of moisture which it embodies, retains the heat but for a short time. A chalky Soil also is heated with difficulty, but retaining less moisture the warmth is not so soon expelled. A black Soil in which soft vegetable matter predominates is most freely heated by the sun and air. Deeply coloured Soils, and such as possess a large proportion of carbonaceous and ferruginous matter, acquire, when exposed to the sun, a higher temperature than Soils of a paler complexion. A rich black mould, containing nearly a fourth part of vegetable matter, when under the influence of sunshine, had its temperature raised in the space of an hour from 65° to 88° of Fahrenheit; while a chalky soil under a similar influence rose only to 69°. The mould being removed into the shade where the temperature was 62°, lost in half an hour 15°; whereas the chalk Soil in the same situation sank only 4°. A cold, fertile Soil and a cold, barren clay, being previously dried, were heated to the temperature of 88°, and afterwards exposed to the air in a place in which the thermometer stood at 57°; in half an hour the former lost 9°, while the other was deprived of no more than 6°. An equal portion of the clay containing moisture was heated to 88°, and then exposed to a temperature of 55°; in a quarter of an hour its heat became equal to that of the room. In conducting these experiments, which were made by Sir H. Davy, the Soils were placed in small tin-plate trays, two inches square and half an inch in depth.*

Of absorption.

The temperature of the Soil, or its power of combining with and retaining heat, is in all cases greatly modified by the property it possesses of absorbing moisture; and this latter quality depends in a great measure on the degree of comminution to which its parts are reduced; for the more they are divided the more active is their power of absorbency. This property is greater in vegetable than in animal substances; and these last possess it in a higher degree than compounds of the earths, and a considerable diversity prevails in the different proportions of the earths themselves. It has been already suggested that the fertility of a Soil has a close connection with its power of drawing moisture from the atmosphere. Experiments to ascertain the extent of this property can be easily made, and a very simple method of determining the relative productiveness of land is obtained by them. "I have," says Sir H. Davy, "compared the absorbent powers of many Soils with respect to atmospheric moisture, and I have always found it greatest in the most fertile Soils. A thousand parts of a celebrated Soil from Ormiston, in East Lothian, which contained more than half its weight of finely divided matter, of which 11 parts were carbonate of lime, and 9 parts vegetable matter, when dried at 212°, gained in an hour, by exposure to air saturated with moisture at temperature 62°, 18 grains.

"1000 parts of a very fertile Soil from the banks of the river Parret in Somersetshire, under the same circumstances, gained 16 grains.

"1000 parts of a Soil from Mersey, in Essex, worth 45*s.* an acre, gained 13 grains.

"1000 grains of a fine sand from Essex, worth 28*s.* an acre, gained 11 grains.

"1000 of a coarse sand, worth 15*s.* an acre, gained only 8 grains.

"1000 of the soil of Bagshot-heath gained only 3 grains."

Water and the decomposing animal and vegetable matter existing in the Soil, constitute the true nourishment of plants; and as the earthy parts of the Soil are useful in retaining water so as to supply it in the proper proportions to the roots, so they are likewise efficacious in producing the proper distribution of the animal and vegetable matter to the expanding fibres of the organized bodies, or plants, which go in search of it, as their natural sustenance.

Soils which repose immediately upon a stratum of rock become much sooner dry by the process of evaporation than when the subsoil is of clay or marl. The contiguity of the strata to the superincumbent layer of earth is supposed to be one of the principal causes of the remarkable fertility of the land in the humid climate of Ireland. A subsoil in which clay predominates is sometimes extremely beneficial to a sandy field in aiding its deficient absorbent power, and supplying the moisture which is lost by the action of the atmosphere and the process of vegetation; while, on the other hand, the excessive degree of absorbent power in a Soil is often corrected by a subsoil of a sandy or gravelly nature. In calcareous Countries, where the surface appears to be a species of marl, the limestone is only a few inches from the Soil; but the contiguity of the rock impairs not its fertility, although a less absorbent Soil in such circumstances would be rendered sterile. This is finely exemplified in the appearance of the sandstone and limestone hills in Derbyshire and North Wales during the summer season; the grass of the former usually exhibits a brown and parched aspect, while the latter are clothed with a rich and beautifully verdant covering.

* *Agricultural Chemistry*, p. 111, &c.

Leaving all the considerations which respect the improvement of land until we come to the subject of manures, we shall now proceed to the theory and practice of draining; following herein what we consider the natural order of events in the improvement and culture of land. It is obvious, indeed, that to whatever purpose the Soil is destined, whether pasture or tillage, it is necessary that it should in the first instance be relieved from superfluous moisture. Even the temporary stagnation of water on arable land may interrupt the usual operations of the husbandman at the most important season of the year, while it can hardly fail to counteract his labours in weeding and manuring, and, in the end, blast all his hopes of a remunerating crop. The produce of grass-lands, too, in which water is redundant, is always coarse and deficient in nutriment; and hence every intelligent farmer directs his first cares to the draining of his fields.

Of Draining.

Geological Principles.

The successful practice of Draining depends in a great measure on a proper knowledge of the Geological structure of the Earth's surface, or of the various strata of which the outer crust, so to speak, is composed, as well as of their relative degrees of porosity, or capability of admitting the passage of water through them, and likewise of the manner in which water is collected in the higher grounds and conducted to those of a lower level. In whatever way the elevations which present themselves on the surface of the Globe were originally formed, it has been clearly shown, by sinking large pits, or by opening quarries in the sides of hills, that they are for the most part composed of beds having an oblique or slanting direction downwards. Some of these strata, from their peculiar properties, allow water to percolate freely through them; while others, so far from admitting a passage, force it along their surfaces without penetrating them in any degree, and thereby compel it to seek an outlet in the grounds below. There, in general, it is obstructed or dammed up, by meeting with impervious materials of some kind or other, by means of which it is raised into the superincumbent layers, if they happen to be open or porous, soon rendering them too wet for the purposes of Agriculture: but where they are of a more tenacious and impenetrable quality, they only become gradually softened by the stagnant water below them; by which, however, the surface of the ground is rendered equally moist and swampy, though somewhat more slowly than in the former case. It may also be observed that some of the strata which constitute such hilly or mountainous tracts are found to be continued with much greater regularity than others; those which are placed nearest to the surface, at the inferior parts of such elevations, being mostly broken or interrupted before they reach the higher parts of them; while those which lie deeper or below them at the bottom, show themselves near the summit. Thus, that stratum which may lie the third or fourth, or still deeper, at the commencement of the valley, may form the uppermost layer at the top of the hill; an arrangement which may have been produced partly by the circumstances attending the original elevation of such mountainous regions, and partly by the fact that the materials of the exterior strata, being dissolved by the action of the atmosphere, by successive frosts and rains, have been carried down into the valleys, and thus left such as were immediately below them in an exposed condition.*

Effects of different strata.

These elevated strata frequently prove the means of rendering the lower grounds wet and swampy; for the general moisture of the atmosphere being condensed in much greater quantities in such elevated situations, the water thus formed, as well as that which falls in rain and sinks through the surface, insinuates itself and thus passes along among the inferior strata which compose the sides of such elevations, until its descent is retarded by some impenetrable substance, such as clay or a very compact rock. It is there collected in a body, and ultimately forced to filtrate slowly over it, or to rise to the light, and to constitute, according to the different circumstances of the case, swamps or marshes in the contiguous valleys. The appearances are more commonly oozing springs, weeping rocks, or sometimes a considerable rivulet formed by the union of small currents under the ground. This is obvious from the sudden disappearance of moisture in some parts of lands, while it stagnates, or remains till removed by the effect of evaporation, on others; as well as from the force of springs being stronger in wet than in dry weather, breaking out frequently after the land has been impregnated with much moisture in higher situations, and as the season becomes drier, ceasing to flow except at the lower outlets. The force of springs, or proportion of water which they send forth, depends likewise in a great measure on the extent of the high ground on which the moisture is received and detained, furnishing extensive reservoirs or collections of water by which they become more amply and regularly supplied. On this account what are termed bog-springs, or such as rise in valleys and low grounds, are considerably stronger and more regular in their discharge, than such as burst forth on the more elevated situations or sides of eminences.†

Modes of ascertain the of moisture.

In Draining land the first thing to be considered is the source of the wetness; whether it be surface-water which from some obstruction is not permitted to pass off freely, or whether it be thrown up, as has just been described, from some of the inferior strata. If a hollow piece of ground be covered with water, or if it should be only wet and spongy during great part of the year and even during the dry season; and, when this ground has been for some time retained in pasture, if the common rush begin to shoot up and thrive on the edges of the wet spot where the soil is somewhat more solid, and if it stretch upwards on the sides of the declivity, and more particularly to a greater height on one side—then the conclusion is pretty certain that the water proceeds from the underground strata, from a bed oft gravel or other porous matter, at some depth under he surface, and supported by an impervious bed, such as a mass or layer of clay. If a pit be dug at the upper edge of the place occupied by the rushes, to the depth of two or three feet —which must vary according to the thickness of the different strata and the depth of the porous bed through which the water filtrates—as soon as the latter stratum is penetrated the water will rise in the pit, and perhaps in a short time overflow and run along the surface. But if a cut, of sufficient dimensions to convey the whole of the water to the nearest ditch, be made, it is probable the wet ground will be relieved from the water, the rushes will disappear, and plants of a very different character take their place. In case no water should appear in the pit, after digging to a moderate depth, or if it should not be convenient to penetrate deeper than a foot and a half or two feet, recourse may be had to the borer or auger; an instrument employed for the purpose of forming a communication with the porous stratum which contains the water, to the depth of many feet or fathoms. When the borer reaches the porous stratum and is withdrawn, the water will be seen to burst up with considerable force and soon fill the pit; and if the communication thus formed continues uninterrupted, the ground becomes dry, and is quickly rendered fit for all the purposes of tillage.

* Darwin, *Phytologia*, p. 258. Loudon, p. 691.

† Elkington, *Mode of Draining*, p. 15.

Mr Elkington's discovery.

To Mr. Elkington is usually attributed the merit of having invented this process of Draining, the origin of which is explained by Mr. Johnstone, the author of the *Account of the most approved System of Draining Land.* "In the year 1763, Mr. Elkington was left by his father the possession of a farm called Princethorp, in the parish of Stritton-upon-Dunsmore, and County of Warwick. The soil of this farm was very poor, and in many places so extremely wet that it had been the cause of rotting several hundred sheep, which was the first means which determined him if possible to Drain it, which he began to do in 1764. The field in which he began was of a wet clay soil, rendered almost a swamp (and indeed in some places a *shaking-bog*) by the springs issuing from a bank of gravel and sand adjoining it, and overflowing the surface of the clay. In order to Drain this field, he cut a trench about four or five feet deep a little below the upper side of the bog, or where the wetness began to make its appearance; and after proceeding so far in this direction and at this depth, he found that it did not reach the *main body of subjacent water* from whence the evil proceeded. On observing this Mr. Elkington was at a loss how to proceed. At this time while he was considering what was next to be done, one of his servants accidentally came to the field where the Drain was making, with an iron crow or bar, which the farmers in that country use in making holes for fixing their sheep hurdles. Mr. Elkington having a suspicion that his Drain was not deep enough, and a desire to know what kind of strata lay under the bottom of it, took the iron bar from the servant, and after having forced it down about four feet below the bottom of the trench, on pulling it out, to his astonishment, a great quantity of water burst up through the hole he had thus made, and ran down the Drain. This at once led him to the knowledge of wetness being often produced by water confined further below the surface of the ground than it was possible for the usual depth of Drains to reach, and induced him to think of applying an auger as a proper instrument in such cases. Thus did the discovery originate from chance, the parent of so many useful Arts! In this manner he not only accomplished the Drainage of this field, which soon rendered it completely sound, but likewise all the other wet ground on his farm."*

His three rules.

The success of this experiment soon extended Mr. Elkington's fame, as a Drainer, throughout the whole Kingdom. From long practice on grounds of every variety of character and situation, he acquired a great facility in judging relative to the nature of the concealed strata and the sources of the hidden springs. The rules on which he acted may be reduced to three: first, finding out the *main spring* or cause of the evil, without which nothing effectual could be done; second, taking the level of that spring, and ascertaining *its subterraneous bearings*, a measure never practised by any till Mr. Elkington explained the advantages to be derived from it; for if the Drain be cut a yard beyond *the line of the spring* you can never reach the water that issues from it, whereas by ascertaining that line, by means of levelling, you can cut off the spring effectually, and consequently Drain the land in the cheapest and most complete manner. And third, making use of the auger to reach or *tap* the spring, where the depth of the Drain is not sufficient for that purpose.

Their application

In proceeding according to this method of Draining, the neighbouring high grounds are to be examined, to ascertain precisely the nature, composition, and inclination of the strata, and their relative position with the land to be improved; from which an opinion can be formed of the nearest point at which the water may be cut off and discharged by the level of the spring. To obtain this necessary information, the beds of the nearest streams, the face of steep banks, pits, wells, and quarries are to be nicely surveyed. Having discovered the main spring, the next object is to determine accurately the line of level in which the Drain is to be conducted. This is one of the most important parts of the operation, and requires particular attention. The last part of the operation is the application of the auger, which is employed in all cases where the outlet, or the expense or the difficulty of execution does not admit the Drain to be cut so deep as to reach the spring.

illustrated.

The Principles now explained will not, we think, be found difficult in application when all the circumstances are fully considered. Suppose there is an extensive flat of swampy land, lying on the bank of a river, and from an examination of the appearances it is concluded that the water is collected from numerous springs, indications of which are distinctly observed on the declivity of the adjoining bank which forms the boundary of the bog on one side; and suppose at the same time that all the springs arise along the upper edge of the wet ground, then, it is very probable, that a single drain conducted in the direction of these springs will effectually carry off the redundant water. But let it be supposed further, that on examining the surface from which the springs issue, they appear at different levels; that the upper series of springs is exhausted in the dry season, while those in the lower part of the declivity continue to flow; the conclusion in this case is pretty evident, that the whole springs are derived from the same source. The lowest are to be considered as the chief springs, and the line of the Drain accordingly is to be carried in their direction, by which the run of water is completely intercepted. If the Drain were carried in the direction of the upper line of springs, it would also answer the purpose, but it would require deeper cutting, and therefore a greater expense would be incurred; or the use of the auger might be required, which by the first method would be entirely superseded. It is scarcely necessary to add that extensive bogs or swamps may require subsidiary trenches in different places to carry off the whole of the water.

---

* Elkington, *Mode of Dr*[illegible] p. 6.

Indications from the soil.

The irregular distribution of the strata of which hills are composed, frequently produces alternate portions of wet and dry ground on the surface. The general aspect of the soil, the nature of the plants, and the degree of wetness which prevails, may, in many cases, indicate the arrangement of the rocky beds, and hence the proper direction of the intended Drain. When the stratum is horizontal or only slightly inclined, all the springs may derive their water from the same source, and when this is exhausted the object will be attained. But in cases where the rock is nearly in a vertical position, and contains partial collections of water in fissures and cavities, it is necessary to carry a Drain to each outlet.[*]

"In many hills composed of alternate strata of rock, sand, and clay, the surface of the latter is commonly wet and swampy, while that of the former is dry and productive, and therefore requires as many cuts to Drain it completely as there are divisions of wet and dry soil. The highest parts of the hill being for the most part composed of porous soil, receive the rain-water which descends through it till it meet some impervious stratum, as clay, which obstructing its percolation any further downwards, it then rises to the surface and forces itself a passage over that impassable stratum. After it has thus overflowed the *upper clay* surface, it is immediately absorbed by the next porous stratum, and descending into it in like manner as above, it again issues at the lower side of it, and injures the surface of the next clay bed as it did that of the first. In this manner, the same stream will affect the other similar strata of which the hill is composed, down the whole declivity, and form at last in the hollow a lake or bog, if there is not a proper outlet or descent to carry off the water. To Drain a hill side of this description, it is necessary to begin by making a trench along the upper side of the *uppermost* rushy soil, which will have the effect of cutting off the highest spring; but as the rain falling on the next porous soil subsides to the lowest part of it and forms another spring, a second cut is necessary there to prevent that water from injuring the surface of the next clay bed. Thus, similar cuts will be requisite down the descent so far as the same springs and appearances continue to injure the ground.[†] See fig. 4, 5, and 6.

The Draining Borer.

The borer used in Draining is nearly similar to that made use of in searching for coal or other subterraneous minerals. The auger, shell, or wimble, as it is variously called, for excavating the earth or strata through which it passes, is from two and a half to three and a half inches in diameter; the hollow part of it one foot four inches in length, and constructed nearly in the shape of the wimble used by carpenters. The rods are made in separate pieces, of four feet long each, which screw into one another to any assignable length which the depth of the hole requires.

Mode of using it.

To judge when to make use of the borer is a difficult part of the business. Some who have not seen it made use of in Draining have been led into a mistaken notion, both as to the manner of using it, and the purpose for which it is applied. They think that if by boring indiscriminately through the ground to be Drained, water is found near enough the surface to be reached by the Drain, the proper direction for it is along these holes in which water has been found; and thus they make it the first implement that is used. But a process directly opposite ought to be followed, and the auger should never be used until after the Drain is cut; and then it should be employed for the purpose of perforating a retentive or impervious stratum, lying between the bottom of the Drain and the reservoir or strata containing the spring. The manner of using it is simply thus: two men above, one on each side of the Drain, turn it round by means of the wooden handle; and when the auger is full they draw it out, and a man in the bottom of the trench clears out the earth, assists in pulling it out and directing it into the hole, and also gives occasional aid in turning with the iron handle or key, when the depth and length of rods require additional force to perform the operation. In one word, the auger may be described as bearing the same relation to dropsical land that the tapping instrument in the hand of a surgeon does to a human patient labouring under *anasarca;* and in both cases the success of the operator is in proportion to his theoretical knowledge of the subject, and the extent of his actual practice.[*]

The invention disputed.

The honour of this discovery, although usually conferred upon Elkington, has not been undisputed. In Dr. Nugent's *Travels through Germany*, printed in the year 1768, there is an account of a mode of Draining land on principles in some respects of a similar nature, not indeed by the use of the auger but by making pits. And in a publication by Dr. James Anderson, entitled *Essays on Agriculture and Rural Affairs*, and bearing date 1775, the author, after describing a mode of tapping by sinking small pits, adds, "I have often imagined that the expense of digging these pits might be saved by boring a hole through this solid stratum of clay, with a wimble made on purpose; but as I have never experienced this, I cannot say whether it would answer the desired end exactly." There seems to be no doubt, however, that Mr. Elkington made use of the auger, prior to the date of either of these publications, or to any hint he could possibly derive from any Work in the English Language, though it is probable that as regards boring the ground for wells, the use of the said instrument was long known in various Countries, especially in Italy. It is proper to observe, at the same time, that although Dr. Anderson's Essays were not published till 1775, the experiments which he describes were made in 1761, and moreover that the account of Mr. Elkington's operations was not committed to the Press till the year 1796. The decision of Parliament, which granted to the latter a reward of £1000, settled the question in a very important point; leaving nothing but empty honour as the subject of controversy.*

---

[*] Elkington, *Mode of Draining*, p. 19. &c.

[†] *Ibid.* p. 43.

[*] A correspondent of the *Quarterly Journal of Agriculture* writes as follows: "Boring with augers and digging wells formed the peculiar features of Elkington's mode of Draining, joined to that of deep cutting; but the latter part only of his mode has been carefully preserved and practised, while the former part has been too much neglected. In one instance of my own in Draining, of which I have had considerable experience, the digging of a well about eight feet deep saved the expense of making a Drain two hundred yards long. Had the well not been attempted at all, that length of Drain must have been cut along a fall of only twenty inches. The well terminated in a thick bed of gravel, which easily absorbed all the water that could possibly have passed through all the Drains connected with it." No. XIII. p. 82.

Surface Draining.

As *surface Draining*, the second department of this branch of husbandry, is conducted on the very obvious principle of having ditches on the lower sides of a field, into which the furrows discharge the superfluous moisture not absorbed by the soil, there will not be occasion for any lengthened remarks. In extensive flats, however, which are covered with water a great part of the year, a more expensive operation becomes necessary. A main Drain, conducted from the intended outlet, must be formed with such a slope and of such a depth as shall be sufficient to relieve the land from so injurious an incumbrance. The course of a Drain of this description, when the inclination of the ground is not perceptible, is formed by the ordinary process of levelling, and in most cases by the use of the spirit-level alone. But without any instrument, those who are familiar with practical Draining can discover the declivity and the course of the water even in land which appears nearly flat, by examining the ditches when they are almost dry in Summer, and by observing to what point the leaves of aquatic plants are directed. When the extent of ground to be freed from water is considerable, a single Drain ought not to be held sufficient. In this case branches from different parts of the field uniting with the main Drain are absolutely necessary; and the number and direction of these branches must be determined by the extent and inequalities of the surface. The subordinate Drains or branches should form a junction with the main Drain in the direction of the current, to avoid the danger of sand or earth accumulating and creating obstructions when they enter it transversely.

Shape of Drains.

We need scarcely observe that the declivity of the ground in many cases must regulate the slope of Drains; but where the outlet and other circumstances afford an opportunity for marking its limits, it should neither, on the one hand, be too great, in which case the sides and bottom exposed to the rapidity of the current might be apt to receive injury; nor, on the other hand, should the inclination of the Drain be too small, by which the current becomes sluggish and stagnant, and the land is not fully relieved from water. A similar discretion must be exercised in the dimensions of open Drains, as such are necessarily varied according to the nature of the soil, the situation, and the quantity of water to be carried off. The width at the bottom of the Drain must be regulated by the proportion of water to be discharged; and it may be stated as a general rule, that the width at top should be at least three times greater, to admit of sufficient slope and solidity to the sides. But in soft and mossy soils even a larger slope is requisite; and wherever the Drain is not meant for a fence as well as a channel for conveying water, the earthy matters thrown out should not be left on the sides to form an elevated bank, but spread on the field or altogether removed. In marshy grounds where the Drain is also required to be a fence, the soil, which should always be thrown out on the lower side, should be allowed to remain; and a small parallel cut may be opened to receive the surface-water from that side, and to conduct it to a convenient place where it may be admitted into the larger Drain.

Open Drains.

In all cases where there is much risk of surface-water being greatly increased in the time of rain, open Drains should always be preferred, to avoid the danger of being entirely obstructed, a casualty to which covered Drains are very liable. But as such Drains, constructed in the usual way, would disfigure an improved field and interrupt the accustomed operations of tillage, they ought to have a greater slope, and a greensward should be permitted to form on their sides. If the direction of the ridges be parallel to the Drain the cultivation of the field is uninterrupted; and when it is in pasture, it presents no obstacle to the free passage of cattle. But the farmer should remember that whatever may be the slope of such Drains, the sides should never be ploughed; for any increased flow of water in that event would carry off the loosened soil.

Hollow Drains in pastures.

When smooth pasture-ground is subject to the collection of surface-water, the evil may be remedied by means of a simple operation with a common plough. Let a deep furrow be turned up through the hollow parts of the field where water stagnates, pare off the earth from the inverted sod, leaving it about three inches thick, and return it to its natural position. In this way a small hollow Drain of three or four inches is left in the bottom of the furrow, which is found sufficient to discharge a considerable quantity of water. By this easy process a great extent of Drain can be executed in a short time; and when any part is obstructed, it can be repaired at a small expense. Lands, again, which are appropriated to woods or plantations, are equally benefited by Draining as those devoted to the production of corn crops, or to the feeding of cattle. For such grounds, open Drains are by far the most suitable; for in covered Drains the roots of the trees, stretching along horizontally, insinuate themselves among the stones, interrupt at first, and finally obstruct the progress of the water.

Drains in a flat soil with clayey subsoil.

The skill of the Drainer is frequently put to the test when he is called upon to remove the superfluous moisture from land which is at once flat and possesses a very retentive or clayey soil. The upper layer of earth being porous readily permits the rain to sink through it while the impervious subsoil prevents it from descending further, and hence the ridges are usually saturated with an excess of water. Land thus circumstanced is described by farmers as being *wet-bottomed*. When the field to be Drained has only a slight declination or slope from the sides towards the middle, one Drain cut through the porous superficial materials into the clay in the lowest part of the ground may be sufficient to bring off the whole of the water detained in the porous soil. This effect may likewise be greatly promoted by laying out and forming the ridges so as to accord with the direction of the land, and by the use of the plough or spade in removing obstructions and deepening the furrows. In such situations, where the Drain has been formed in this manner, the water will flow into it through the porous surface-materials as well as if a number of small trenches were cut from it to each side, as is the practice in Essex and some other parts of the country; but which is often an unnecessary labour and expense. The Drain made in the hollow may frequently serve as a division of the field, in which case it may be open, but in other circumstances it may be more proper to have it covered.

---

* See Elkington, *Mode of Draining*, p. 10, where the following notice is inserted. "Buffon states that, in the city of Modena and for miles round, whatever part is dug, when we reach the depth of sixty-three feet, and bore five feet deeper with an auger, the water springs out with such force that the well is filled in a very short space of time. The water flows continually, and neither diminishes nor increases by the rain or drought."

When a field of this description has more than one hollow in its surface, it will obviously be requisite to have more than one main Drain; but when it is nearly level or only inclined slightly to one side, a trench or Drain along the lowest part, and the ridges and furrows formed accordingly, may be sufficient for effecting its Drainage. There may, however, be cases, as where a field is large and very flat, in which some side cuts in the principal Drain may be necessary, which must be dug a little into the clay, and as narrow as they can be wrought, and then filled up with stones or other suitable materials. What is called the Essex method of Draining in ploughed, springy lands, where the surface soil is tenacious, is described by Kent, and consists in substituting small under Drains for open furrows; or in some cases having a small under Drain beneath every second or every third furrow. These Drains lead to side or fence ditches where they discharge themselves.

Draining a clayey surface.

Where the clay constitutes the surface and the porous body is underneath, the injurious stagnant water cannot possibly get off without the assistance of Drains formed for the purpose. Soils of this nature are Drained with difficulty and require a much greater number of trenches or cuts than those of any other kind, as they must be marked out and disposed in such a way as to collect and convey the water every where from the surface; because it can only force itself off into them from above, being prevented from sinking in through the clay as in soils of a contrary kind. Where there happen to be hollows or irregularities in the surface of the land, water may often be observed to continue standing in them at a distance of but a few feet from the Drain. In Draining such lands it will always be necessary in the first place to make a large or conducting Drain at the lowest part, or the end of the field, for the purpose of receiving and conveying away the water collected by the smaller collateral cuts which it may be necessary to make on each side of it. Where it suits for the purpose of dividing the land, this principal Drain may be better open than covered, as by that means the mouths or outlets of the different small Drains that come into it may be conveniently examined, and cleared out when necessary.

Construction of ridges.

The construction of the ridges in such soils so that they may accord with the declivity is a matter which must be carefully kept in view. They should in all such cases have a degree of elevation or roundness in the middle, sufficient to afford the water a ready fall into the furrows, which likewise should have such a depth and fall, as may take it quickly into the Drains. The ridges, being well laid up, should have small open Drains formed in a slanting direction across them in such a manner as to form communications with one another and with the furrows; by which means they are made to perform the office of Drains; the water coming upon the ridges being thus readily conveyed into the furrows along which it proceeds, till impeded in its course by the ground or other cause; it then passes through the open cross Drains into others where the descent is greater, and ultimately into the ditch or other passage at the bottom of the enclosure. The elevation of the ridges should probably, too, be made greater for the Winter than the Summer crops, as there must be much more injurious moisture at the former than the latter season.*

This may be easily accomplished at the time of ploughing the land.

Of the different kinds of Drains used by Agriculturists we may mention those which are formed of stone, brick, gravel, cinders, wood, spray, straw, turf, and tile. See fig. 7 to 13.

Rubble Drain.

The first of these, or the common *rubble* Drain, is formed of rough land-stones of any sort, broken so as not to exceed two or three inches in diameter. No good drainer uses stones six or eight inches in diameter in any part of a rubble Drain, least of all at the bottom. The point kept in view is to use such small stones at the bottom as may allow the water a great many channels; so that if a few should become impermeable, there should be many others remaining. The nearer the bottom of a Drain of this kind approaches to the character of a natural bed of gravel, the more certain will be the free passage of the water. Gravel or ashes should be laid on the top of the stones, on these a thin layer of straw or haulm of any kind, and the remainder filled up with the surface soil.

Brick Drain.

The *brick* Drain is formed in a great variety of ways, either with common bricks and bats, in imitation of the boxed and rubble, or rubble Draining, or of bricks made on purpose, of which there is great variety.

Gravel Drain.

The *gravel* or cinder Drain is seldom made deep, though if the materials be large they may be made of any size. In general they are used in grass-lands; the section of the Drain being an acute-angled triangle, and the materials being filled in, the smallest uppermost, nearly to the surface of the ground.

Wood Drain.

The *wood* Drain is of various kinds. A very sufficient and durable construction consists of poles or young fir-trees stripped of their branches, and laid in the bottom of the Drain lengthways. They are then covered with the branches and spray. Another form is that of filling the Drain with faggot-wood with some straw over. A variety of this mode is formed by first setting in cross-stakes to prevent the faggots from sinking; but they are of no great use, and often occasion such Drains to fail sooner than common faggot Drains. In some varieties of this Drain, brushwood is first laid down at its side, and formed by willow or other ties into a continuous cable of ten or twelve inches in diameter, and then rolled in; which is said to constitute an excellent Drain with the least quantity of materials, and to last a longer time than any of the modes above mentioned. Some cut the brushwood into lengths of three or four feet, and place them in a sloping direction, with the root end of the branch in the bottom of the Drain. Others throw in the branches at random with little preparation and cover them with spray, straw, or rushes, and finally the surface soil.

Spray Drain.

The *spray* Drain is generally, like the gravel Drain, of small size, and formed like it with an acute-angled bottom. In general the spray is trodden firmly in; though in some cases it is previously formed into a cable, as in the brush-wood Drain. Drains of this sort are much in use in grass-lands, and when the spray of larch wood, heath, or ling can be got, they are of great durability.

Straw Drain.

The *straw* Drain, where reeds, rushes, and bean-straw are used, is sometimes made like the spray Drain, by pressing the loose materials down or forming a cable; but in general the straw is twisted into ropes as big as a man's leg, by the aid of a machine, and three or more of these are laid in the bottom of a triangular Drain, with or without the protection of three turfs; where some sorts of moss, as *sphagnum* or *lycopodium*, can be got, these Drains are of very great durability.

---

* Loudon, p. 704. Marshal *on Landed Property*, and Dr. Anderson's *Treatise on Draining*.

Turf Drain

The *turf* Drain may be made of any convenient depth, but it must be at least the breadth of a turf at bottom. The Drain being dug out, as if it were to be filled with stones or any ordinary material, the operator next, with a spade three inches wide, digs a narrow channel along its centre, clearing it out with the Draining scoop; and over this the turfs are laid without any other preparation or any thing put over them, but the earth that was excavated. This is found to be very cheap, and, considering the materials, a surprisingly durable method of Draining; answering in pasture-fields especially all the purposes that the farmer can expect to derive from Drains constructed with more labour and at a much greater expense. They are said frequently to last twenty years and upwards; but the period during which they will continue to prove effectual, must depend on the nature of the soil and the current of water.

in Cheshire.

A mode of turf Draining used in Cheshire is described as follows: the surface of the ground, in which the Drain is intended to be cut, is marked out in parallelograms about the size of bricks on one side, while the opposite side to the width of nine inches, or that of a common sod, is left unbroken. These sods are taken out at a spade's depth, and laid carefully by the side of the Drain for covers. The other sods, resembling bricks in their size and shape, are then dug, and laid carefully on the same side as the sods intended for covers. The Drain is then sunk to the proper depth, and the stuff taken out is thrown to the other side. The bottom is levelled with proper draught for the water, and set with the sods like bricks, two in height on each side; these are covered with the larger sods set obliquely, the grassy sides being turned downwards.

Wedge Drain.

The *wedge* Drain is constructed as follows. When the line of Drain is marked out, a sod is cut in the form of a wedge, the grass side being the narrowest, and the sods being from twelve to eighteen inches in length. The Drain is then cut to the depth required, but is contracted to a very narrow bottom. The sods are then set in with the grass sides downwards, and pressed as far as they will go. As the figure of the Drain does not suffer them to go to the bottom, a cavity is left, which serves as a water-course; and the space above is filled with the earth thrown out. The work is performed by means of three spades of different sizes. The first may be a common spade of moderate breadth with which the surface clay may be taken off to the depth of eight or ten inches, or not quite so much if the clay be very strong. The breadth of the Drain at top may be from a foot to fifteen inches; but it never should be less than a foot, as it is an advantage that the sides should have a considerable slope; and the two sides should slope as equally as possible. Another workman follows the first with a spade six inches broad at the top, and becoming narrower towards the point, at which it should not exceed four inches. The length of the plate of this second spade should be fourteen inches, and with it a depth of a foot or fourteen inches can easily be gained. A third workman, and he should be the most expert, succeeds the second, and his spade should be four inches broad at top, only two inches broad at the point, and fourteen or fifteen inches in length. With this spade a good workman can take out at least fifteen inches of clay. A sort of hoe or scoop, made of a plate of iron, formed nearly into the shape of a half cylinder of two inches diameter, and a foot or fourteen inches long, and fastened at an acute angle of perhaps 70° to a long wooden handle, is now employed to scrape out the bottom of the Drain, and remove any small pieces of clay that may have fallen into it. The grassy side of the turfs being turned undermost, they are put down into the Drain, the workman standing upon them after they are put in, and pressing them down with his whole weight till they are firmly wedged between the sloping sides of the Drain. The ends of the turfs being cut somewhat obliquely, they overlap each other a little; and by this means, although there is a sufficient opening for the surface-water to get down, nothing else can find its way. The open space below the turfs ought to be five or six inches in depth, three inches wide at top, and an inch and a half or two inches at bottom.[*] The author of the above communication remarks, that wherever sufficient attention has been paid to keep the ditches at the ends of the field clear, so as not to choke up the mouths of the Drains, (a point of great consequence,) they appear to have succeeded very well, and he feels confident that wherever the soil is filled for the purpose, the work properly executed, the Drains of a sufficient depth, and no improper treatment or neglect on the part of the farmer, these Drains will answer the most sanguine expectations. He thinks that they should never be less than three feet deep, otherwise they are apt to give way, either from moles getting down into them in very dry weather, or from the feet of the horses employed in ploughing, when the ground is wet, sinking so far as to injure the turf.

Earth Drain.

The *earth* Drain, called also the *clay-pipe* Drain, is better calculated for the purpose of conveyed water already collected than for drying the soil. A Drain is dug to the necessary depth, narrow at bottom, in which is laid a smooth tree or a cylindrical piece of wood, ten or twelve feet long, six inches in diameter at the one end and five at the other, having a ring fastened in the thickest end. After strewing a little sand upon the upper side of the tree, the clay or toughest part of the contents of the trench is first thrown in upon it, and then the remainder, which is firmly trodden down. By means of the ring and a rope through it, the tree is drawn out to within a foot or two of the small or hinder end, and the same operation repeated. A gentleman who has tried this experiment says, that this clay-pipe has conducted a small rill of water a considerable way under ground, for more than twenty years, without any sign of failing. Pipe Drains of turf are sometimes formed where the surface soil is a strong clay, as it is only turfs from such a surface that are sufficiently durable. A semicylindrical spade is used to dig the turfs, and hence the turfs themselves resemble a hollow cylinder divided in two. The Drains being dug to the proper depth, one turf is laid in the bottom of it, and another being placed over, completes the pipe or conduit. The same sort of pipe Drain has been formed out of solid beds of clay, and has also served for a time to convey water.

Tile Drain.

The *tile* Drain is used in flat, clayey soils where stones are scarce, and where the declivity is small. The tile fabricated for this purpose is much more concave than that used for roofing houses, resembling, indeed, the form of a sugar-loaf or obtuse cone; and the price, according to the size, varies from twenty-four shillings to £3 the thousand. In laying out the line of Drains, where it is intended to cut off springs, the usual system is followed. Where the removal of surface-water is the object in view, the natural inequalities, or indentations on the face of the field, are carefully examined, so as to attain the end with as few Drains and with as much effect as possible. Where very stiff clay exists, a Drain even in every furrow, or division of ridges, has been resorted to with much success, and the expense is not so great as might appear at first sight. In other cases, where the soil is of a damp, retentive nature, where the surface is flat and incumbent on a stiff clay, in which there are no springs, main Drains may be run in the lowest parts of the land to be dried, and smaller Drains connected with these, running parallel to each other at stated distances. This mode, when properly executed, answers the purpose in view remarkably well.

---

[*] *Transactions of Highland Society*, vol. vi. p. 568.

Tile Draining at Netherby.

In the *Transactions of the Highland Society* there is an account given of this mode of Draining as practised on the estate of Netherby in Cumberland. The deepness has always been suited to the object in view; Drains for springs in many cases have been very deep, so as to cut through the substratum containing the water, whether that has been gravel or sand; surface Drainage for two feet and a half to four feet and a half deep. In all cases the Drains are cut as narrow as a man can conveniently work in them, decreasing in width as they approach the bottom. The tools used are the common spade, shovel, and pick, or the round-mouthed spades used in forming canals, which in Cumberland are known by the name of navigation spades. The Drains being cut to the required depth, with all the top-soil laid on one side, and all the subsoil thrown out on the other, a narrow-mouthed spade, technically called a spit, corresponding to the breadth of the tile to be used, is then introduced; and with this instrument a bed for the course of the tile is neatly and carefully excavated, the strictest attention being paid to preserve a fair equality in the bottom, and a regular descent for the water; while a frequent use of the spirit-level is most commonly indispensable. But the mode of procedure will be distinctly comprehended by referring to fig. 14.

"A, the Drain cut to any required depth. B, the space for the Draining-tile. C, a bit of slate or broken tile, on which the tiles rest at their joinings; a precaution which may be omitted where the bottom is a very stiff clay. D, a clean-cut, green turf, the grass side next the tile, and clapped carefully over it, to prevent the tile from receiving any damage. E, E, the surface soil, cut out of the top of the Drain, and put above the turf. The remainder of the Drain is filled up, if wished, by the subsoil excavated, or what is more general, this soil is spread on the adjoining ridges, and the sides of the Drain are then sloped in by the spade. Straw, furze, or small brushwood, are sometimes placed next the tiles, but a clean good turf is preferable. It has in some few cases been the practice at Netherby, when the Drains happened to be very near the river, and carriage of course not expensive, immediately after the tiles were placed, to fill up the Drain with the clean blue stones from the bed of the Esk, which are here very small, to as great a depth as was thought necessary, and then to finish off the Drain in the usual way of closing stone Drains. This probably makes the best of all Drains; but with tiles alone the result has been most gratifying on all the varieties of soil mentioned, where the Drains are carefully executed. It has been customary here to use the auger where the tapping of springs was thought necessary."*

Expense.

Expense of Draining by three-inch tiles.

	Per rood of 21 feet.	
Cutting the Drain, say on average 2 feet 9 inches deep, laying the tiles on slate or refuse tile, cutting and laying a turf over the tile, reversing the surface-soil, and covering in	0*s.*	4*d.*
Tiles. 21 to the rood, say at the price paid at Netherby for three-inch tiles, 24*s.* per thousand	0	6¼
Carriage of tiles, average distance three miles, three loads a day, a cart carrying 250, and at 5*s.* per day for horse and cart	0	1¾
Refuse slate, broken tile, and carriage............	0	0½
Per rood	1	0½

Calculating in the same way, it is found that the expense of Draining by four-inch tiles amounts to one shilling and three-pence halfpenny the rood of twenty-one feet; and that a similar process with tiles six inches in the span will cost one shilling and five pence farthing per rood; the cutting in these cases being from four feet and a half to five feet in depth. But it is added that the three-inch tiles are decidedly the most useful for ordinary purposes. The four-inch tiles are able to discharge a very considerable quantity of water. The six-inch tiles, unless the spring is very strong, or the Drains of great length, are not so much used as the two last sorts; while eight-inch tiles are seldom or never necessary, unless in very particular situations.

Advantages.

This mode of Draining answers uncommonly well in the clay lands of Essex, where the soil is firm and retentive, and where the superfluous moisture does not issue from below, as in more porous grounds. We ourselves are acquainted with a district on the banks of a large river, where the common method of Draining cannot be rendered available owing to the low level of the fields, which has been much improved in its productive qualities by the use of tile Draining. A small channel is constructed in every furrow, supplied with this artificial conduit, and covered to the depth of fifteen or eighteen inches with earth, so as to protect it from the feet of the horses when engaged in ploughing. If the tile be made of proper clay and well burnt, it is found to last many years; and it is acknowledged by the farmers who have had recourse to this expedient, that their crops are so much benefited by it, that they could afford to repeat the operation every three or four years.

Pearson's pipe Drain.

There is a method of *pipe* Draining which takes its name from Mr. Pearson, and has been described in several publications, more especially in the XLVIIth volume of the *Transactions of the Society of Arts*. The ground is first opened by means of a plough, having what is called a horn share. With four horses, a furrow nine or ten inches deep by ten inches in width is raised or taken out. The horns are then removed, the coulters added, and eight horses attached. This cuts the soil to an additional depth of ten inches, and it is immediately removed with narrow spades, and larger or smaller Draining scoops, as may be required. A second pair of coulters cuts the soil to the intended depth, in which case also the earth is taken out by the scoops. The total depth is now about twenty-six inches, the width at top ten inches, and at bottom about one inch. A slide is then dropped to the bottom of the Drain, commencing at its lowest level so as to work up hill. A windlass is next placed at the full length of the rope which is attached to the slide. Clay is next rammed firmly down on the slide with a heavy rammer, to the depth of three or four inches, and the slide is next pulled forward, leaving a cylindrical Drain, three or four inches in diameter, according to that of the slide.

---

* Highland Society Essays in *Quarterly Journal of Agriculture*, No. 6. p. 395.

Its application.

This is, in effect, the same as that described above under the denomination of the earth or clay pipe Drain; the mode of forming the excavation and the conduit being alone different. It is obvious, at the same time, that the efficacy of this, as well as of the former, depends entirely on the nature of the soil, and the source of the moisture which it is the object of either to remove. Surface-moisture is excluded by the very structure of the Drain; for no sooner should it penetrate the clay than the tube would collapse or crumble down. But if the intention of the farmer extends no further than to convey water already collected on some particular spot to a rivulet or main Drain, the contrivance of Mr. Pearson will be found to realize his views at less expense than any other.

Wheel Drain.

The *wheel* Drain is the last we shall mention, which, though like some of the others limited in its application to particular kinds of land, is yet too ingenious to be passed over without notice. It is accomplished by means of a Draining-wheel of cast iron, weighing about four hundred weight. It is four feet in diameter; the cutting-edge or extremity of the circumference of the wheel is half an inch thick, and increases in thickness towards the centre. At fifteen inches deep it will cut a Drain half an inch wide at the bottom, and four inches wide at the top. The wheel is so placed in a frame that it may be loaded at pleasure, and made to operate to a greater or less depth, according to the resistance made by the ground. It is used in Winter when the soil is soft; and the wheel tracts are either immediately filled with straw ropes, and lightly covered over with earth, or they are left to crack wider and deeper till the ensuing Summer; after which the fissures are filled with ropes of straw or of twisted twigs, and lightly covered with the most porous earth that is at hand. In this way, upon grass or ley lands, hollow Drains, which answer extremely well, are formed at a trifling expense. It is said that twelve acres may be fully gone over with this Draining-wheel in one day, so as to make cuts at all necessary distances.*

Ridges.

These resources of Art are found availing in a great number of cases, and have contributed much to the improvement of land which otherwise would have been of very little value. Still, in many instances where the surface is flat, and the soil of a stiff and retentive nature, all attempts to free the ground from injurious moisture by means of covered Drains have proved utterly ineffectual. In most of the central Counties of England, and in the level plains of Flanders, the land is relieved from surface-water by forming high and broad ridges of twenty, thirty, and even forty feet wide, and having the centre three or four feet more elevated than the furrows. The beneficial effects of this method of Draining are fully confirmed by the successful practice of the Flemings; for when furrows are kept free from water, the fields are always dry, and the crops abundant and healthy. But in some parts of England, from the improper direction and flatness of the ridges, as well as the shallowness of the furrows, these good effects have not been obtained; for the water, stagnated in all the hollow places, and rendering them useless, has not only brought some degree of discredit on the method itself, but has also led to the adoption of other less perfect methods of Draining. The indiscriminate formation of high ridges has been justly censured, for in a dry or loamy soil they are both unnecessary and pernicious; but when they are well rounded, not too much raised, and the furrows kept clear, they afford the most efficacious means of rendering perfectly dry many fine breadths of land which could not otherwise be kept under tillage.

Draining in the Carse of Gowrie.

A device for relieving a retentive soil from water by means of surface-draining, as it is practised in the Carse of Gowrie in Perthshire, seems worthy of being recorded in this place, more especially as it is the only method employed in that rich and extensive district. Large common Drains, traversing the farm in different directions, and of sufficient capacity to receive the water conducted from the fields by the surrounding ditches, discharge their contents into the river Tay. Every farm is surrounded or traversed by ditches, so as to suit the particular situation, all of which are so directed and arranged as to form a communication with every field belonging to it. The breadth of these ditches is from two to four feet at top, and from a foot to a foot and a half at bottom, and with such a slop as to prevent their sides from falling in. If the fields be of a uniform level surface, the common furrows between the ridges, provided they have sufficient depth at their extremities, serve to carry off the redundant water. But in a field of unequal surface, the last operation, after the sowing and harrowing are completed, is to draw a furrow with the plough through all the hollows which lie in such a direction that it can be guided through them, and thus form a free communication with any of the furrows between the ridges, which last act as conductors of the water to the surrounding ditches. When this furrow is formed by the plough, it is widened, cleared out, and dressed with the spade, that the risk of filling up may be avoided. The width is from six inches to a foot according to the depth; but the breadth of a spade at bottom is generally found sufficient. It often happens that hollows or inequalities do not extend across the whole field, or pass through it in any direction to be followed by a plough, but are limited to one or two ridges; in which case the cut must be performed with the spade, and a communication effected with the nearest furrow.

Head-ridges.

In the same part of the country, it is still the general practice to have head-ridges at two extremities of the field, on which the horses turn in the process of ploughing. These are raised considerably in the middle, and slope down to a deep furrow on either side; and hence the inner furrow, communicating with those of all the longitudinal ridges, receives their surface-water, and discharges it by an open Drain, cut through the transverse or head-ridges just described, into the adjoining ditches. But it being discovered that the water passes off more freely when no transverse ridge is formed, a practice has been adopted of laying the earth uniformly to the ends of the longitudinal ridges, an operation which is accomplished by returning on one side with an empty plough. In this way the depression between the longitudinal and transverse ridges is avoided, the longitudinal furrow being carried completely through the head ridge. Besides this advantage, it has been found, after a long experience, and the trial of different other methods, that, by careful ploughing, laying up the land equally, and rounding the ridges so skilfully that they shall be neither too high nor too low, all the surface-water is easily removed; and while the summits are not unduly enriched nor the furrows impoverished, the whole becomes equally dry and fertile.*

---

* *Agricultural Report of the County of Essex.* London, p. 710.

Tools. Draining scoop.

The tools peculiar to Draining are chiefly of the spade kind. The *Draining scoop*, already mentioned, is a crooked instrument made use in some cases for clearing out the loose materials from the bottoms of Drains. It is formed of different sizes and breadths, according to the dimensions of the Drains; and in working, it is drawn or pushed along the bottom. See fig. 15.

Shovel.

The *Draining shovel* is another kind of tool employed for nearly the same purpose as the scoop now described. It is made with a bent or crooked handle; the edge of the plate being turned up so as to prevent the fragments of earth or clay from falling off when lifted from the bottom of the Drain. See fig. 16.

Sod knife.

The *Draining sod knife* is an implement employed with great benefit in scoring or cutting out the sward, in the initiatory process of forming a Drain. Its figure indicates that it cuts like the coulter of a plough, placed horizontally, or after the fashion of a Turkish sabre. See fig. 17.

Spades.

Draining spades are of different sizes in breadth as well as in length, so as to follow each other, and cut the Drains narrower and narrower as they approach the bottom. An upper and a pointed Draining spade are in general use; the one for beginning, the other for completing the work, while one constructed entirely of wood is found to answer very well in peat soils. See fig. 18.

Straw-twister.

The *Draining straw-twisting machine* is of a very simple construction, is easily removed, and is very useful for forming straw into ropes for filling Drains. It consists of a small wheel, the prolonged axis or spindle of which terminates in a hook on which the rope is commenced. It is commonly fixed to a portable stand, but is sometimes attached to a threshing machine. Besides the use already stated in reference to Drains, it is found extremely convenient for spinning ropes of straw, rushes, or hay, to be employed in fastening the thatch or stacks, or ricks in the barn-yard. See fig. 19.

Irrigation.

Necessity.

The fertilizing effect of water is one of those natural phenomena which force themselves on the observation of mankind. It is seen, at the first glance, to be absolutely essential to vegetable life. In those climates in which evaporation is the greatest, Nature has generally provided the most plentiful supply of this fluid in rains and dews. But the rains, in many cases, occurring only at particular seasons of the year, are insufficient for the nourishment of plants during the remainder; and, hence, the art of the Irrigator becomes necessary to meet this want, and to secure the means of a more permanent fertility. Without the systematic conveyance and distribution of water, some of the richest Countries in the World could not have supported their inhabitants, and the earliest husbandmen, accordingly, must have known and practised the cultivation of land by means of Irrigation. Antiquity. The author of the Book of *Ecclesiastes* informs us that he "made gardens and orchards, and planted trees in them of all kind of fruits; and that he made pools of water to water therewith the wood that bringeth forth the trees." Egyptian. In Egypt, where the regular inundation of the Nile soon taught the natives the value of this Art, we find it practised on a scale of great magnitude; and hence the canals and vast lakes excavated by that celebrated people are more praiseworthy monuments of their genius than all the Temples and Pyramids with which they have covered a large portion of their Country. From the valley of the Nile, it is believed, the knowledge of Irrigation was extended to the nations of Europe. Greek and Roman. The Greeks and Romans, it is manifest, were well acquainted with it; and the Agricultural writings of the latter, accordingly, are found to contain many allusions to the benefits arising from the watering of land. Rice, which furnishes food to a great part of the human race, could not, as is well known, be cultivated without a constant supply of water collected by Art; and therefore over the vast regions of Central and Southern Asia, Asiatic. the Irrigation of the soil from rivers, brooks, tanks, and wells, is a labour quite indispensable to the maintenance of a crowded population. European. Even in the more Southern Countries of Europe this Art is more or less practised; water being conveyed in little channels to the corn-fields, vineyards, and olive plantations. The mode of conducting it from the rivers and canals, and the measuring it out in determinate quantities, according to the wants of the soil, and the nature of the crop, forms in several districts of Italy a nice part of the Science of engineering. In Piedmont and the whole valley of the Po, the water is frequently paid for by the hour, and the utmost care is shown in economizing so precious a commodity.

Objects.

The main object of Irrigation, however, in all the intertropical climates, and even in the warmer parts of the temperate zones, seems to be merely to convey to the earth that quantity of water which is necessary for the growth and nourishment of the particular plants which it is the object of the husbandman to raise. Sometimes, as in the case of rice, the land must be saturated for successive months, and, in other circumstances it is enough if it be merely watered at intervals, during the periods of greatest evaporation. In all these cases, indeed, the main purpose is the same, namely, to supply the deficiency of water in the soil; and this creates a remarkable distinction between the Irrigation of the tropics, and that to which we apply the term in England, with relation either to our watered meadows, or the process which in some districts of the Kingdom is technically called *warping*. in England. As to the former of these it is perfectly certain that the object is not to provide against a want of moisture in the soil, for the water is conveyed over the surface at that period of the year, the months of Winter, when there is an excess rather than a deficiency of the aqueous fluid in the earth. Nay, it is held necessary in every well-formed meadow, to drain the ground very thoroughly of all subterraneous water. Nor is this the only distinction between the two kinds of Irrigation. In the one, the water is generally allowed to stagnate until it shall have saturated the soil; in the other, it is never allowed to stagnate, but is maintained in a constant flow over the surface.

Uncertainty of its Theory.

The theory of this curious process has not yet been satisfactorily explained. That the effect is not produced by the mere supply of deficient water appears, as we have just remarked, not only from the period at which the water is admitted, when in our climate the ground is saturated with moisture, but also from the fact that the effect is produced by the current being kept constantly running over the meadow, and not by being allowed to stagnate and sink down into the soil. When the water is suffered to stagnate, there are produced *carices*, *junci*, and other plants of an aquatic nature; but when it is kept in motion and drained off at intervals, there shoot forth the finest grasses peculiar to the soil and climate. Neither does the fact of the deposition of mud explain the phenomenon in question, for, however much such depositions may increase the effect, it is found that water likewise, without the least perceptible sediment, may be employed with great benefit. It has been supposed that the water acts favourably by maintaining the soil at a higher temperature than it would retain if exposed to the direct action of the atmosphere. Much, however, cannot be ascribed to this cause in a current so shallow and constant as that which passes over the watered meadow. It has, therefore, been suggested that the main effect is produced by some Mechanical or Chemical agency, in a manner still unknown to us, on the plants or the soil. In these circumstances of doubt and ignorance all that the irrigator is called to do, is to mark carefully the effects which are produced, according to the variations of his practice, to admit the water at the time and for the periods which experience points out as the best, to maintain it in a current, and not in a stagnant state; and above all, to attend to the rules and precautions which the most enlightened usage has recommended.

---

* Elkington, *Mode of Draining*, p. 172. Appendix on Hollow Draining by Mr. Johnstone, the editor of his book.

Necessity of experience.

We may, therefore, rest satisfied with this practical conclusion, that as land may be injured by an excess of moisture, so may it, in certain circumstances, as experience has proved, be found deficient in its productive qualities from the absence of a due *proportion of it*. In all Countries Southward of the forty-fifth degree of latitude, the study of the landholder, as has been already remarked, is more frequently directed to the means of procuring aqueous nourishment to his plants than in conveying away, by drains, the superabundant supply by which the British Agriculturist is almost constantly annoyed. The success of the former during the hot season of the year, depends in no small degree on the command which he possesses of lakes or rivulets by means of which he may Irrigate his parched fields, and restore life to his decaying crops. In this Country the various processes of Irrigation are applied chiefly to the improvement of pasture lands, but there are situations also where a deposition of earthy matter from the water of a river is esteemed useful for fertilizing a sandy soil; on which account we shall treat the subject generally as applicable to both these departments of Agricultural economy, tillage and the feeding of cattle in the field or in the stall.

Quality of the water.

The quality of the water fittest for this purpose must be tried by experiment, for it is obvious that the benefit is not derived simply from an increase of moisture, but more especially, as has been suggested, from the Chemical properties of the fluid as cooperating with those of the soil on which it is spread. Let a small portion of land be floated for a month about the latter end of harvest, and afterwards for a week or two about the beginning of Spring. The effects of this easy experiment will appear on the crop, both in respect of quality and quantity, while the temperature of the water may be determined by its power of resisting early frosts, a consideration of no small consequence in this mode of improving land. The appearance of the water is not of itself sufficient to afford a criterion of its properties. Thick muddy rivers, enriched in their passage through large towns, will be found to reward the labour of the husbandman; while clear Alpine streams, on the other hand, will chill instead of fertilizing the soil on which they are detained. With regard to those waters, again, which are known to flow through beds of marl, there is reason to believe that much advantage may be gained from the use of them, in producing a sweet and rich verdure the most valuable for pasturage. Warm rivulets, containing a great quantity of spring water, and resisting early frosts, may be expected to have the same beneficial tendency. But mossy waters, darkened by the tincture of peat bogs, are very unpromising for the purposes of Irrigation; though it may be right in some cases to give them a trial, for if impregnated with marl, or spread upon grounds abounding with calcareous ingredients, they will be productive of certain benefit.*

Sir H. Davy's remarks.

It is observed by Sir H. Davy, that common river water generally contains a certain portion of organizable matter, which is much greater after rains than at other times; and which exists in the largest quantity when the stream arises in a cultivated country. But even in cases in which the water used for flooding pasture lands is pure, and free from animal or vegetable substances, it acts by causing the more equal diffusion of nutritive matter existing in the land; and in very cold seasons it preserves the tender roots and leaves of the grass from being affected by the frost. Water is of a greater specific gravity at 42° of Fahrenheit's scale than at 32°, the freezing point; and hence, in a meadow Irrigated during Winter, the water immediately in contact with the grass is rarely below 40°, a degree of temperature not at all *prejudicial to the living organs of plants*. "In 1804," says he, "in the month of March, I examined the temperature in a water-meadow, near Hungerford, in Berkshire, by a very delicate thermometer. The temperature of the air at seven in the morning was 29°. The water was frozen above the grass. The temperature of the soil below the water in which the roots of the grass were fixed was 43°." In general, it is added, those waters which breed the best fish are the best fitted for Irrigation. It is, however, a general principle, that waters containing ferruginous impregnations, though possessed of fertilizing effects when applied to a calcareous soil, are injurious on such as do not effervesce with acids; and that calcareous water, which is known by the earthy deposits it affords when boiled, is of much use on silicious lands, or other soils not containing any remarkable quantity of carbonate of lime.†

To pursue the subject a little more systematically, we shall consider the effects of Irrigation, *first*, as it applies to corn lands, and *secondly*, as it respects those which are used for pasture, as well as for raising crops of hay.

Irrigation on corn lands. Warping.

1. The process, as applicable to the former, is commonly called *warping*, a provincial term, the meaning of which will be best explained by the description which follows. In some districts it is justly considered as one of the principal means of improvement, adding to the value and thickness of the soil every time it is repeated. In fact, a new soil is artificially created by the operation in question, and generally one much superior in quality to the surface which it is brought to cover. It is not indeed in every situation that warping can be used, but

---

* Brown *on Rural Affairs*, vol. ii. p. 265.

† *Agricultural Chemistry*, p. 318.

wherever it is practicable it ought to be employed, if the land be not already saturated with the elements of fertility. The expense, it must be obvious, will vary according to circumstances, but even when at the greatest, it is not to be compared to the immense benefit which is thereby conferred upon thin and hungry soils.

Originated in Yorkshire.

Best adapted to low lands.

Fittest seasons.

It was in Yorkshire that warping originated, and there it is still carried on to a great extent, especially on the banks of the Quse and of the Humber. The former of these rivers, from the circumstance of receiving into its bed most of the streams which intersect the Southern parts of that County, is constantly stored with all sorts of alluvial matter; and being kept in motion by the tide which flows several miles above York, the floating earths are not allowed to deposit themselves, but are conveyed by the process of warping over the adjoining grounds, which for the most part are flat and easily flooded. Of all others, low land is the most capable of being improved in this manner; and while it is enriched by so simple an expedient, no injury is inflicted upon such farms as are placed beyond the reach of the benefit. June, July, and August are considered to be the best months for warping, on account of their being generally the driest months in the year; though land may be warped at any season, provided the weather be not wet, nor the fresh water in the river very low. When the season is wet, and the rivers full, the operation of warping cannot be conveniently executed, as the fresh water, mixing with the tide, dilutes the current to a great degree, and consequently renders it incapable of depositing the same quantity of sediment upon the land as takes place when the process is performed in fine weather; neither is the water got so readily off the irrigated grounds. There is no advantage in warping land in the Spring, in preference to the Summer, as no crop can be obtained the year this expedient is adopted; for the sediment must have time to consolidate and dry before the ground can be cultivated with any prospect of doing good. Warped land is supposed to be well calculated for producing potatoes, immense crops of that valuable root being raised on soils so managed, though naturally of a very inferior order.

Strict definition.

From what has been stated, it will be understood that *warp* consists of the mud and salts left by the water on the surface of the fields which have been flooded; and that the technical expression *warping* comprehends all the processes necessary to admit the tide water, and to secure the deposit of its sediment upon the land meant to be improved. The letting in of fresh water would not be called warping, but simply flooding. Fresh water, though useful at proper seasons, would by no means answer the same purpose as river water stirred up by the tide; because it never could furnish a sufficient sediment for thickening the soil; neither would the sediment be of so rich a nature as what is furnished by tide water.

Mode of operation.

A complete detail of the different operations in the process of warping is given in the *Agricultural Survey of the West Riding of Yorkshire.* From that Work it appears that the land to be warped must be banked against the river whence the supply of water is derived. The banks are commonly made of earth taken on the spot, are constructed in a sloping form, and are raised to such a height as to regulate the admission of water at the spring-tides. The openings are more or less numerous, according to the extent of the land to be warped; but in general there are only two sluices, the one called the *flood-gate,* the other the *clough;* the object of the first being to admit, while that of the last is to let off the water gently, during the rise and fall of the tide in the river. When the spring-tide begins to ebb, the flood-gate is opened to admit the current, the clough having been previously shut by the weight of water brought up the river by the flow. As the tide ebbs down the river, the weight or pressure of water being taken from the outside of the clough next the bank, the tide-water which has been previously admitted by the flood-gate, opens the clough again, and discharges itself slowly but completely through it. The cloughs are so constructed as to let the water run off, between the ebb of the tide that was admitted and the flow of the next; a point to which particular attention is paid, and the flood-gates are placed so high as to be above the level of the common tides, and so as to receive the water only at the springs.

Willow planting

It is not unusual to plant willows on the sloping sides of the banks, with the view at once of breaking the force of the stream, and by producing an accumulation of mud of defending them from the action of the water. But the experienced husbandman avoids all such plantations on the top of his banks, knowing that he would thereby give to the winds a great additional power, and expose his works to much serious damage.

Deposit.

Subsequ culture.

Quality o the land.

We need not remark that the deposit is made by the ebbing tide, as the rush from the ocean rather checks the current which comes down loaded with the spoils of the land from the higher parts of the country. Near Howden, it is said, one tide will deposit *warp* to the depth of an inch; an effect which is increased or diminished according to the distance from the mouth of the Humber. Cherry Cob Sands were originally gained from this river by warping, and are supposed to possess a deposit of alluvial sediment not less than twelve feet deep. They were ploughed fourteen or sixteen years before they became fitted for grass seeds; but now the greater part of the tract is used for pasture, and yields a most nutritive herbage. Grass-land, we are assured, is not warped a second time, until the plants are found beginning to wear out; upon which the process is commonly renewed, the water is again admitted, the plough once more stirs its surface, and a succession of corn crops are drawn from the renovated soil, before it reverts, as in the first instance, to the uses of pasture. It is true that the best mode of cultivating warped lands must depend principally on the nature of the matter deposited as well as of the subsoil. In the *Code of Agriculture,* it is recommended to sow such grounds with clover, and to let it lie under that crop for two years, in order that it may be brought into a fit state for corn. Even though fallowed, it does not answer to sow land with wheat immediately after it has been warped; but after white or red clover for two years, a good crop of wheat may generally be relied on. Nor is it proper, says the same authority, when land is warped, to plant it with potatoes, or to sow it with flax; being at first of too cold a nature; though if the land be not too strong for potatoes, these crops may answer, after it has been two or three years under cultivation. In the quality of warped land, we need not add, there are most essential differences; some is found very strong and some very friable even in the same field. The portion nearest the sluices and the general run of the water, is commonly the lightest, owing to the quantity of sand that is deposited as soon as the current enters the enclosure; while that furthest from the river bank is usually the best, as the deposit takes place more undisturbed, and in much greater abundance.

South of France and Italy.

The Irrigation of arable land, as we have repeatedly observed, is universal in warm Countries, and even in the South of France and Italy. It is laid out in narrow beds, between which the water is introduced in furrows during the growth of the crop and absorbed by the soil. The principal expense of the operation is that of preparing the ground by throwing the surface into a proper level. The main run, or carrier, as it is called, is conducted to the highest part of the field, and all the rest is easy. In the *General Report of the Agriculture of Scotland*, it is stated, that a field of waste land, which had been flooded during Winter with stagnant water, was thereby rendered capable of bearing a plentiful crop of oats, without the use of any species of manure. But this process, it has been justly observed, partakes more of the nature of warping than of simple Irrigation, particularly as the latter is practised in India, and in the Southern parts of Europe, during the course of vegetation.

Subterraneous Irrigation.

There is a species of Irrigation which is denominated *subterraneous*, to distinguish it from that which has just been described. It appears to have been first practised in Lombardy, and is mentioned by Professor Thouin, in the *Annales du Musée*. As its name imports, it consists in saturating the soil with water from below, and is effected by surrounding a piece of ground with an open drain, and intersecting it by covered channels of smaller dimensions. If the field is one level, as happens in most cases where this system is adopted in Italy, nothing more is necessary than to fill the drain, and to keep it full till the land has been sufficiently soaked. But if it lies on a slope, then the lower ends of the smaller drains must be closely stopped, and the water admitted only into the main one on the upper side; this last must be kept full till the land be saturated, when the mouths of the lower drains may be opened to carry off the superfluous water. The practice is applicable either to pasture or to arable lands, under a climate more distinguished for heat than moisture.

In Britain.

In our own Country subterraneous Irrigation has been applied, in a very simple manner, to drained bogs, morasses, and fen lands. All that is necessary is to build a sluice in the lower part of the main drain, where it leaves the fields to which attention is directed, and in dry weather to shut this sluice, so as to dam up the water and throw it back into all the subsidiary drains, whether covered or uncovered. This method has been introduced with great advantage in various parts of Scotland, and also in Lincolnshire, where extensive drainages have lately been accomplished.

Irrigation of grazing lands.

2. But in these Northern latitudes, Irrigation is much more frequently applied to grazing-grounds than to such as are meant for tillage. For the former, the original quality of the soil is of little importance; wherever the water deposits a good deal of sediment, the natural poverty of the surface being soon fertilized by the enriching ingredients with which it is imbedded. This observation, it is true, respects the meadows of England more directly than the artificial pastures of Scotland; for, in the latter Country, the streams for the most part descend from barren hills, and, accordingly, convey hardly any other deposit than silicious sand and coarse gravel.

Various grasses produced.

The author of the Work entitled *Rural Affairs*, who has evidently bestowed much attention on the Irrigation of various soils, recommends to his readers the following results as the fruit of experience. He has found that perennial red clover prospers in watered meadows, having a due proportion of marl or lime in the land itself, or in the water with which it is moistened, while the common broad red clover speedily dies out; that the plants of *Holcus lanatus*, the soft, vernal, woolly, meadow grass, prosper in any soft soil, especially if it be also watered; that *Poa trivialis*, the rough-stalked meadow grass, delights in the soils last mentioned, if they are possessed of a degree of moisture between loam and bog; that *Cynosurus cristatus*, the crested dog-tail grass, thrives extremely well in watered loams, although Botanists seem not aware of this fact; that *Anthoxanthum odoratum*, scented vernal grass, will hardly fail in any watered meadow where it has been once established, however coarse may be the soil, adding not only to the bulk and weight of hay, but communicating the sweetest odour to the whole crop, if made in dry weather; that the genus of grasses, called *Agrostis*, or *bent*, furnishes two species which are very good plants in watered meadows, the *Agrostis alba*, and the *Agrostis stolonifera*; that in loams completely broken with the spade, and then watered, *Triticum repens*, couch or quick grass, forms a valuable plant for hay; and that for soft peat bogs, no plant yields more hay than the common spratt, the *Juncus articulatus*, which in richly watered meadows comes forward very early, and would scarcely be known, if mown before feeding, by those who never saw it cut in proper time.

"All these plants," says Mr. Brown, "are adapted to furnish a crop of hay, and also to yield a very abundant pasturage; but at present they can hardly be obtained in the seed-shops, excepting perennial red clover, which is sold under the name of marl grass. A farmer must have a portion of good grass, or purchase it from others; leaving it to stand till the seeds are mostly ripe, and then taking care to preserve these for sowing in his new meadow grounds. I have not often met with perennial rye grass in watered meadows, and am inclined to think that it does not prosper there; but as I know that it will stand for a season or more, it may be soon intermixed, and will thicken the grass in the mean time."*

Season.

The water should be let on early in the month of October. The effects of this watering are very important in strengthening the roots and stalks of plants, and preparing them for vigorous shoots in the Spring; and the blades that now rise form a rough coat against Winter, protecting the more delicate organs of the vegetable frame from the severity of that season. It sometimes happens, also, that by delaying the process too long early frosts supervene, and very much impede, or even entirely defeat, the main object of the operation. If the land be rich, it will generally be found that three weeks are sufficient for the first turn; but if it be sour and coarse, four weeks may be necessary. The verdure will then be fine, and the soil rich and yielding.

Method of conducting water.

To apply Irrigation judiciously to meadow land, a stream of water must be conducted to the surface and made to flow over it in a constant manner; it being understood that the grounds to be so treated lie upon the banks of the river from which the supply is to be conveyed, and forming a flat surface, or rather a gently inclined plane. To the highest part of this inclined surface, the water is led in what is termed the main conductor, either by building a wear or dam across the river where the water is to be taken off, or by bringing it by means of a cut from a higher source. In fig. 20, A represents the main-conductor, and B the wear or dam.

---

* Brown, *On Rural Affairs*, vol. ii. p. 263, &c.

From the main conductor, and as nearly as possible at right angles to it, are taken off the various feeders, C, C, C, &c. These consist of small trenches a few inches in depth, made widest when they issue from the main conductor, and gradually lessening as they recede from it. They may be formed at the distance from each other of forty feet or less, being closer where the soil is stiff and retentive, and further distant where it is loose and porous. By this means the water is conveyed to the surface of the meadow. But as it is necessary that it should maintain an equal flow over the ground, and so be carried off as quickly as it is admitted, the main drain D, D is formed at the lower part of the meadow, and the smaller drains E, E, E pass in the intervals between the feeders, in the manner exhibited in the diagram already referred to. These small drains are of the same dimensions as the feeders, but are larger where they enter the main drain, and become gradually smaller as they recede from it. The main drain conveys the water back to the river from which it was taken; but in many instances, this drain becomes, in its turn, the main conductor to another meadow on a lower level. The water which had floated the upper meadow being collected in this drain, is carried off from it by means of feeders in the manner described, and again collected in a drain below; and, in this manner, various meadows are successively irrigated by the application of the same water. Even where the lower meadows are nearly on the same level as the higher, it is still expedient to resort to this repeated collection of the water in drains; for, in practice, it is found difficult to preserve the equal flow of the moisture over a large breadth of ground.

In order to keep the water as it descends through the feeders at the necessary level, and to cause it to overflow the surface, it is interrupted in its progress by what are termed stops, placed in the feeders. These sometimes consist of small pieces of plank, each resting on two little stakes. But oftener they are merely sods thrust into the feeders and occasionally fastened with wooden pins. It is the province of the person who superintends the meadows, when floated, to adjust these stops in such a way as to maintain an equal current over the whole surface. Further, in order to convey the water quickly from the feeders to the drains, the face of the meadow is generally moulded into low ridges, the feeders being on the top of the ridge and the drain in the hollow, so that a transverse section would appear, as in fig. 21; *a* representing the feeder, and *b b* the drains. In the language of the scientific Irrigator, the interval from *b* to *a* is termed a *pane;* and in fig. 20, the space *i i*, which is left for a carriage way above the main conductor, is denominated the main pane, and is watered from that conductor.*

On grounds much inclined.

Such is the most perfect form of the watered meadow. But when the inclination of the plane of the surface is considerable, a different principle must be adopted as regards the conveyance and distribution of the water. In this case the feeders are not carried longitudinally through the meadow, but across the line of the descent, in the manner represented in fig. 22. Here the several feeders are filled as before from the main conductor, but when they overflow their banks instead of discharging their water into the smaller drains, they throw it into the next feeder lower down; and thus the fluid is conveyed from feeder to feeder over the entire space of the meadow. This species of Irrigation is termed *catch work;* and, as it can be applied where the surface is too much inclined to admit of the flat meadow, it is frequently practicable where the other is not, and is often combined with it on the same ground, where there are swells or considerable inequalities.

Periods.

We have remarked above that the process of floating generally commences in the month of October, being as soon as possible after the later grass is consumed, or the second crop of hay removed. The water is kept in the ground from fifteen to twenty days at a time. It is then let off, and the meadow laid perfectly dry during five or six days; and this process of alternate flooding and drying is continued generally in the months of November, December, and January; care being taken to remove the water whenever it begins to freeze. As the Spring advances and the grasses shoot forth, the periods of watering are shortened so that the flooding shall not last above five or six days at a time. In the Southern Counties of England, the meadows are ready for the reception of stock of all kinds in the middle of March; but further to the North, where the grasses do not make such early progress, Irrigation is usually continued during the whole month of May. After this it is discontinued for the season, and a crop of hay, sometimes two, are produced to reward the farmer for his pains. Flooding is rarely practised during the Summer months, though the admission of water at that season occasions a rapid and profuse vegetation. It is suspected that it is by Summer flooding the fatal disease of rot is introduced; and accordingly the experienced Agriculturist does not permit his sheep to graze on the meadows which have been covered with water any time between May and September.

Roman knowledge of Irrigation.

England, it has been remarked, is the natural Country of the watered meadow; being perhaps the only one where the practice of the Art is understood and carried on as a regular branch of rural labour. There is no room to doubt that this branch of knowledge, like many others, was derived from the Romans. For though in modern Italy the Irrigation practised seems merely designed to convey water to the soil, yet from various remarks in the writings of the ancient authors, it would appear that those illustrious husbandmen were acquainted with the principles of that more artificial process of which we now speak. It is well known that a great preference was given by many of the Romans to the meadow as compared with corn land, as being more profitable to the occupier. The maxims of the elder Cato on this subject, have been handed down to us, and are often quoted. He speaks frequently of the watered meadows: *Prata irrigua, si aquam habebis, potissimum facito; si aquam non habebis, sicca quam plurima facito.* "If you have water irrigate as many meadows as possible; if you have not water, make as many dry meadows as you can." Pliny, Columella, and Palladius express themselves to the same effect. But to whatever skill the citizens of Rome may have attained, prior to their conquest of Britain, there are circumstances peculiar to England which have conduced more to its perfection here than even in Italy, where, in our days at least, natural meadows are more rare, and where all that is required to fulfil the highest purposes of the husband man is to convey a little water, no matter how, to the parched surface of his fruitful soil. This Country is, in particular, admirably suited to the production of the common grasses. These appear in a variety of species unknown in more Southerly climates, and grow with a closeness and vigour unparalleled in higher latitudes. The rivers, too, especially in those Counties most celebrated for this branch of husbandry, are generally turbid, and, flowing through fertile and cultivated districts, are enriched with the animal and vegetable matters which they receive in their progress, and thus not only irrigate, but positively manure the lands to which they are conveyed. Gloucestershire and Wilts have long been celebrated for their superior Irrigation; and there are now other divisions of the Kingdom not inferior to them in the extent and perfection to which the practice has been carried.

---

* Stephens, *Practical Irrigator. Quarterly Journal of Agriculture,* No. VI. p. 781.

Irrigation not much practised in North of Britain.

In the Northern Counties of England, as well as in those beyond the Tweed, this mode of improving land has not hitherto been very generally adopted. Perhaps the diminished temperature is unfavourable to Irrigation; while the rivers, rushing over a rocky bed and between precipitous banks, do not afford the same facility for inundating, in a regular, periodical manner, the adjoining fields or meadows. An attempt was made in Dumfrieshire some years ago; but the result, owing to ignorance and prejudice among the tenantry, or perhaps to local peculiarities which could not be controuled, was very little encouraging. The vicinity of Edinburgh, we are informed by Mr. Stephens, presents almost the only exception in Scotland to the remark just made in reference to want of success in the processes of Irrigation. About two hundred acres moistened by the common sewers of the city, "produce crops not to be equalled, being cut from four to six times in the year, and the grass given to milch cows." The annual rent of those meadows ranges from £20 to £40 per acre, according to the convenience of the situation, and the care bestowed on the land; nay, he mentioned an instance in which the price rose so high as £57 the acre, for a single Summer.*

Edinburgh.

Manures.

Division.

No sooner is land relieved from the deteriorating effects of superfluous moisture, than it is fitted for the application of those animal or vegetable substances which, when reduced to a putrescent state, are known under the general name of Manures. Our limits will not permit us to enter into the minute details which might be desired by the practical Agriculturist; but whatever deficiency may appear to arise from the abridged nature of our plan will, we hope, be amply compensated by copious references to the best authors who have treated this important subject. To assist the comprehension of the reader we shall arrange our observations under the five following heads: Calcareous, Earthy, Vegetable, Animal, and Miscellaneous.

Calcareous Manures. Lime.

The most common form in which calcareous matter appears is that of lime, a substance than which there is none more familiar, whether as an article employed in the Arts, or as used for the purpose of improving land. As it exists in Nature, it is always in a state of combination with an Acid, the carbonic or sulphuric, and not unfrequently with clay and silicious earth. When limestone is subjected to a strong heat, the gaseous matter with which it is combined is expelled, and it is found to have lost a portion of its weight equal to that of the elastic fluid which has escaped. When the burned mass is exposed to a moist atmosphere, it absorbs water, swells, and falls down into a powder, denominated quick-lime, and which is more or less pure according to the nature of the stone. It has, moreover, acquired new properties. Limestone, although pounded down to a fine sand, has no perceptible effect on animal or vegetable matters; but burned or calcined lime is extremely acrid and corrosive; and hence the distinctive characters of this mineral in its two states as *mild* and *caustic*.

Estimate of purity.

As limestones have very different degrees of purity, it is obviously of the highest importance to ascertain the quantity of calcareous matter which enters into their composition. In general, then, it may be observed, that the greater the loss of weight which they sustain in burning the larger is the proportion of pure lime. A pretty accurate estimate may be made of the quantity of calcareous matter in any limestone, by observing first, how much diluted nitric or muriatic Acid is required for the complete saturation of a determinate portion of the purest limestone; and secondly, by ascertaining how much of the limestone to be examined will saturate an equal amount of the same Acid. If in the latter case a double quantity is found necessary, then the stone contains only half the quantity of the calcareous earth which is in combination with the purer specimen. But practical Agriculturists usually have recourse to a simpler and more obvious test; which consists in the measurement of the burnt lime in the unslaked state, as compared with its bulk in the state of powder after it is slaked; the latter being three times the volume of the former when the limestone is of a good quality.

Soils.

The soils which are most improved by the use of lime are those usually denominated cold and stiff, such as strong clays and deep loams, or such as are combined with a large proportion of vegetable matter, but contain no calcareous earth in their composition. It may, indeed be regarded as advantageous to all lands except such as display sandy or calcareous ingredients. Considerable diversity of opinion prevails indeed as to the time and circumstances in which lime ought to be applied. But, in whatever way it operates, whether by its mechanical effects on the soil, altering its consistence and texture, or by certain Chemical changes on the organized matter contained in the Globe, there can be no doubt that, in order to produce the desired result, it must be equally and uniformly distributed over the surface of the field. To ensure this object, the lime must be in the form of powder, and in as dry a state as possible. For this purpose the calcined stones should be laid together in considerable heaps; and as they absorb moisture from the earth or atmosphere, they gradually swell and fall to pieces. Might it not be suggested as a useful and convenient method for the equal application of lime to mix it carefully with a quantity of dry earth? and if mould of a different nature from the soil to be improved could be easily obtained, the increased value of the compost as a means of fertilizing the land, would doubtless be an ample compensation for the additional labour and expense.

Mode of application.

As lime cannot produce its effects without being intimately mixed with the soil, it follows that it should not be applied except when the latter is dry, and in as complete a state of pulverization as can be accomplished by the operations of tillage. Another general rule to be observed in the use of this Manure, is that it should be mixed with the soil near the surface. The most proper time for its application, therefore, seems to be when the operations of fallowing are concluded, when it may be either harrowed in, or covered with a very light ploughing. On the same principle lime is best applied to lands destined for turnips, wheat, and similar crops, immediately before the deposition of the seed, so that a moderate harrowing is the only operation which remains to be performed. Repeated ploughings are recommended by some authors for the purpose of mixing calcareous Manure thoroughly with the soil; but there is no small risk that a part of it shall be thereby carried down beyond the reach of vegetation, an effect very frequently produced when grass lands are limed and then subjected to a deep furrow.

---

* *Practical Irrigator.*

Season for top-dressing.

When lime is to be used as a top-dressing for pasture land, it should be applied early in the Spring or Autumn, rather than in Summer or Winter; because in hot weather the grass is apt to be burned up, while in Winter the effects of this Manure are supposed to be diminished by the frost.

Renewals.

It is deserving of notice that great care is requisite in renewing the application of calcareous matter to the same field, even at a considerable distance of time; for it has been found that, on soils where it produced, in the first instance, the very best effects, the repetition of it, in the same quantity, has either not been attended with any beneficial result, or with one positively injurious. Hence it has become in many parts of the country an established maxim to apply lime in proportions constantly decreasing, and always in the form of compost with other earthy or animal substances.

Quantity.

No precise rule can be laid down as to the quantity of this Manure which should be applied to every particular species of land. The general practice seems to proceed on the principle that light, sandy, or loamy, require a smaller portion than stiff clays; but in no case is the determinate quantity accurately ascertained. The quantity employed in some parts of the Kingdom, and on certain soils, ranges from five hundred to a thousand bushels for the imperial acre; though the average may be estimated at rather less than two hundred bushels. In the Peak of Derbyshire, the largest proportion just mentioned is not unfrequently expended on the heaths and moorlands, by means of which they are converted into excellent pasture. But it has been justly remarked that, in many instances, though an overdose of lime does no harm, it is not beneficial to the full extent, and therefore can only be regarded as an injudicious expenditure.

Mixture with magnesia.

The caution now recommended is more necessary in those parts of the country where the limestone is mixed with magnesian earth, which never fails to have a deleterious effect on the crops. It communicates to the calcined powder an extremely caustic quality, whence it has usually been distinguished both by the mason and the farmer, as *hot lime.* Mr. Tennant was the first who traced this corrosive action to the presence of magnesia in the form of a carbonate. The quantity employed as Manure ought not to exceed thirty bushels the acre, except where there is, in the land, a large proportion of vegetable matter not fully dissolved, in which case the dose may be somewhat increased. When the magnesia is mild, or in other words, has not been burned, it is acknowledged to be a useful ingredient in the composition of soils. The Lizard Downs in Cornwall, which bear a short, green grass, and afford an excellent pasture for sheep, contain a considerable quantity of mild magnesian earth.

Theory of operation.

It is remarkable that, although the good effects of lime properly applied are so obvious as to recommend it to the Agriculturist as one of the most useful Manures, its mode of operation, whether on the soil or plants, remains still a secret. Numerous speculations have been indulged in regard to it; but until Chemistry and Physiology shall have made further advances in unfolding the changes which take place in the qualities of the mould, and in developing some of the mysteries of the vegetative process, we must consider the whole as only doubtful conjecture. "When lime," says Sir Humphry Davy, "whether freshly burned or slaked, is mixed with any moist vegetable matter, there is a strong action between the lime and the vegetable matter, and they form a kind of compost together, of which a part is usually soluble in water. By this kind of operation, lime renders matter, which was before inert, nutritive; and as charcoal and oxygen abound in all vegetable matters, it becomes at the same time converted into carbonate of lime. Mild lime, powdered limestone, marls and chalk have no action of this kind upon vegetable matter; by their action they prevent the too rapid decomposition of substances already dissolved, but they have no tendency to form soluble matters. It is obvious from these circumstances that the operation of quick-lime, and marl, or chalk, depends upon principles altogether different. Quick-lime, in being applied to land, tends to bring any hard vegetable matter that it contains into a state of more rapid decomposition and solution so as to render it a more proper food for plants. Chalk and marl, or carbonate of lime will only improve the texture of the soil, or its relation to absorption; it acts merely as one of its earthy ingredients; quick-lime, when it becomes mild, operates in the same manner as chalk, but in the act of becoming mild, it prepares soluble out of insoluble matter. It is upon this circumstance that the operation of lime, in the preparation for wheat-crops, depends, and its efficacy in fertilizing peats, and in bringing into a state of cultivation all soils abounding in hard roots, or dry fibres, or inert vegetable matter."

Pounded limestone.

In cases where caustic lime is not found to answer, the farmer sometimes applies pounded limestone, which, as has just been suggested, improves the soil by becoming one of its earthy ingredients. The scrapings or dust of roads formed of this rock have been used with advantage as a Manure, in Yorkshire, Gloucestershire, and other districts; a circumstance which leaves no doubt, that were machines employed for grinding the carbonate into a powder sufficiently fine, the consistence of much indifferent land might be greatly ameliorated. On the same principle, the dust of marble-works and even the smaller fragments in limestone quarries, have been found beneficial, in the absence of more active calcareous elements.

Limestone gravel.

Limestone gravel has been found an excellent Manure for peat-bogs; its weight consolidating the loose soil while its fertilizing qualities augment the produce. It has proved of immense benefit to Ireland and also to some parts of Scotland. Chalk, we need hardly observe, is used to a great extent in the Southern and Eastern districts of this Kingdom, where it presents itself in great abundance. It is frequently applied in a crude state, spread upon the surface in Autumn, and left to be dissolved by the frost during the Winter.

Five or six waggon-loads per acre produce a very beneficial effect; though, when calcined, two hundred bushels may be allotted to the same extent of ground, and even repeated every three or four years.

Marl.

Of *marl* there are usually reckoned four kinds, rock, slate, clay, and shell. In Lancashire and Cheshire, clay-marl is very much used by the farmer, who does not grudge a considerable degree of labour and expense in order to obtain it. The quantity laid on the ground, from time to time, appears enormous; amounting, in many cases, to three hundred cart-loads per acre, which give to the fields the semblance of a red-soiled fallow freshly ploughed. Shell-marl consists entirely of calcareous matter, being the broken and partially decayed remains of testaceous fish. It may be applied as a top-dressing to wheat and other crops when it would be hazardous to use quick-lime.

Sea-shells

Sea-shells abound in various parts of the British Isles, and are frequently collected as a Manure. They are superior to the usual sorts of limestone in purity, and in the proportion of calcareous matter which they contain. These shells have not, however, unless when burned, an equally rapid and powerful influence on the soil. When not calcined they are much improved in their effects, if broken in a mill resembling that used by tanners for bruising their bark; the air which is thereby admitted accelerating their decomposition and consequent mixture with the proper ingredients of the field. Sea-sand having a mixture of shells is also used with much success on the shores of Yorkshire, Devonshire, Cornwall, Caithness, and Aberdeen. It is particularly beneficial in strong clays, as both its component parts, sand and shells, have a powerful tendency to improve a stiff soil.

Gypsum.

Gypsum, or the sulphate of lime, when applied to the cultivated grasses, is generally found to reward the labours of the husbandman. The ashes of sainfoin, clover, and rye-grass, when those plants are calcined, afford this substance in considerable quantities; and hence it has been inferred that it constitutes a necessary part of the woody fibre of those grasses. Cultivated soils in general contain enough of it for the grasses they produce; but where there is any deficiency, fields which have ceased to bear good crops of clover and other artificial grasses, may, it is presumed, be restored to their former fertility by a suitable application of this mineral.

Earthy Manures.

2. The *Earthy Manures* are of a very simple nature, and do not require any scientific explication either as to their ingredients or use. We have already intimated

Clay.

that clay is sometimes advantageously employed in improving the texture of a loose sandy soil; the quantity being determined by the degree in which the argillaceous properties are absent, in every particular field which requires to be so treated. Burned clay has likewise been long known as an excellent expedient for fertilizing grounds on which other Manures have exhausted their efficacy. In a comparative experiment, made in Galloway, of raising turnips by means of stable-dung and of clay-ashes, the crop in the ground manured with the ashes sprang earlier, was more vigorous, and the turnips were double the size. In another experiment in the same district, a very abundant crop of turnip was obtained. The quantity employed varied from thirty to fifty cart-loads per acre. Mr. Parsons, near Sherborne, applied from fifty to sixty bushels to the acre, on a cold, wet, cohesive soil. Mr. Buckley, in the neighbourhood of Loughborough, employed about seventy cart-loads to the acre of a stiff soil, in which he thought its effects in improving the texture and communicating permanent fertility were more striking than in any other instance which fell under his observation. The ashes of burned clay have also been applied as a top-dressing to grass lands, and are said, when spread at the rate of forty tons to the acre, to produce very striking effects.

Sand.

Sand, as has also been suggested when treating of calcareous substances, is now commonly used for improving the composition of stiff clayey soils. But sand, taken from the mouths of rivers or the shores of the ocean, as it frequently contains a portion of animal and sometimes of vegetable matter, is the most likely to promote their fertility. The sands of flat shores, covered with water only during high spring tides, and which are strongly impregnated with common salt and other saline ingredients, are in some places washed for the extraction of the salt, and afterwards spread on the land as manure.

This double manufacture is pretty general on the Northern side of the Solway firth; and it is manifest that the latter practice might be advantageously adopted in many other situations. The rubbish of houses, too, which is usually a mixture of sand and lime, with other earthy and occasionally saline material, constitutes a valuable Manure, and in all cases ought to be carefully collected and preserved. Loam, mould, or any mixture of different earths with a portion of organized substances, when added to a sterile soil of a different quality, produce during a few seasons the most beneficial effects.

Peat-ashes.

Peat-ashes have long been celebrated as an efficient Manure in several parts of England, especially in Berks and Wiltshire. They contain a considerable proportion of gypsum, together with calcareous, aluminous, and silicious earths, the sulphate and muriate of soda, and sometimes a little of the oxide of iron. Dutch ashes, which are highly recommended by Sir John Sinclair, in his *Account of the Husbandry of the Netherlands*, are composed of nearly the same ingredients, and are applied as a manure to clover which is succeeded by wheat. Nineteen bushels to the English acre afford an abundant crop of both. Burned peat is applied as a top-dressing for cultivated grasses, particularly sainfoin and clover, at the rate of from thirty to forty bushels per acre. Nay, we find that the dust of dried rotten peat is in some soils an excellent manure for potatoes. It is cut to pieces as if intended for fuel, and after being exposed to the atmosphere for some time, is laid upon the land.

Coal-ashes.

Coal-ashes, too, although rarely employed unmixed with other substances, afford an abundant source of Manure in the neighbourhood of all large towns. The ingredients of these ashes vary in their nature and proportions according to the quality of the mineral whence they are produced; but they consist generally of aluminous and silicious earths, with a small quantity of lime and sometimes of magnesia. They are found to be highly beneficial in correcting the tenacity and opening the texture of clayey soils. They are of particular use in the neighbourhood of London, for improving those lands from which bricks have been dug. After spreading the ashes on the clay bottom, horsebeans, or some variety of the garden bean, are planted; and sometimes such grounds are laid down in grass. When applied as a top-dressing to clover, March or April is the best season, and the quantity should not exceed sixty bushels to the acre.

Ooze.

Under the head of Earthy Manures, we may class the ooze, mud, or warp, which is procured at the mouths of rivers, in ponds and canals. It is of a most enriching nature, and adds to the staple of the soil. It is used as a top-dressing in Spring for crops both of grain and grass, more especially for the latter; being at the same time an excellent material for composts. The late Duke of Bridgewater made considerable use of sea-ooze, brought up from the Mersey, in barges, by his canal, to lands near Worsley. It has been remarked, that wheat raised by means of this Manure is little subject to rust, mildew, or any other distemper. In respect to the mud of ponds and fresh-water streams, the value of it depends upon the substances with which it is mixed. Where the water is resorted to by cattle or fowl, or receives the washings of towns and farm-yards, or even the drainage of a rich tract of country, it will display considerable fertilizing powers, and amply repay the expense of collecting. In the Netherlands, the gardeners maintain that the mud of canals and rivers is much improved in its quality, when it has been exposed, in small heaps, to a Winter's frost and a Summer's sun before being applied to use.

Vegetable Manures. Ploughing down green

3. In giving a list of *Vegetable* Manures, we naturally begin with that which is produced by ploughing down green crops, such as clover, buck wheat, vetches, beans, turnips. When this method is adopted, a portion of lime, or of peat and lime mixed together, should be spread on the field before the succulent plants are turned down; a process which ought to be performed in the Summer or early part of the Autumn, that the decay of the vegetable fibres may be more speedily promoted. In cases where Manure is scarce, this practice may be found useful; but it has been suspected that, on the whole, its advantages are doubtful, for although the quantity of nutritive matter may be increased, the expense of the acquisition seems too great.

Sea-weeds.

Sea-weeds, in some districts, are a most important Manure, and when used with judgment never fail to enrich the land, though the effects, it is admitted, are not very lasting. They may be procured either by cutting them from the rocks, or by gathering the leaves and branches which are cast ashore by the tide; in both cases, they ought to be ploughed down without loss of time, as their efficacy appears to depend in no small measure upon the degree of freshness which they possess when mingled with the soil. The value of this Manure in improving old pastures is generally admitted. Both cattle and sheep eat with avidity the new grass which is thereby produced, thrive well, and fatten quickly.

Weeds.

Weeds, taken from rivers, ponds, and ditches, when properly decomposed, form an ingredient of a very fertilizing compost. The heaps should be thrown together as lightly as possible, and sprinkled with water in a dry season. A small quantity of lime, or of peat earth, mixed with them, during the process of solution, not only increases the bulk, but adds materially to the value of the Manure. The more intelligent farmers confine the use of this material to fields prepared for barley, or for turnips, to be sown broad-cast.

Malt-dust.

Malt-dust has also been found very beneficial to soils of a certain description. It is much improved by being spread for some time in the bottom of pigeon-houses, in farm yards, and also in such tanks as receive the urine of cattle, the moisture of dunghills, and the refuse of the kitchen and wash-house. It is usually sown by the hand, when in a dry state, to the extent of about thirty bushels an acre, and harrowed in with the seed, whether barley or oats.

Rape-cake.

Rape-cake has long been used in this Country, especially in Norfolk and Yorkshire. Half a ton for an acre was formerly the amount applied to arable land; but since the price of the article has increased, the rate is reduced to one ton for three acres. Mr. Coke of Holkham makes a single ton suffice for five or six acres, by breaking the cake into very small pieces, and ploughing it in about six weeks before the time of sowing, that it may be completely dissolved in the ground. When ploughed in with wheat seed, the effect is very striking in a speedy and vigorous crop. This Manure is very extensively used in the Netherlands. It has been found that, when powdered and strewed on the surface of a field, it destroys the *Gryllus talpa*, so injurious in wet soils; and it is imagined that every insect might be exterminated by the same means. A ton of oil-cake, whether from rape or any other seed, mixed with twenty or thirty tons of dunghill compost, constitutes an excellent manure.

Tanners' bark.

Tanners' bark has been recommended by certain authors as a substance which may be rendered nutritive to plants. For this purpose it must undergo the process of fermentation, which is most easily accomplished by forming it into a compost with stable dung. The addition of a little lime cannot fail to assist in the disintegration of the woody fibres.

Wood ashes.

Wood-ashes have been already alluded to, under the head of Earthy Manures. They are peculiarly well calculated for gravelly soils and loams. Forty bushels per acre is the common quantity, and Spring is the proper season for their application. The effect is much increased by moisture, whether natural or artificial, which seems necessary, either as a menstruum or a vehicle, for communicating the fertilizing qualities. It has been remarked, that whatever passes through the fire acquires the power of exciting or increasing the productive properties of land.

Animal Manures.

4. *Animal substances* are usually so soluble in their nature as not to require any chemical preparation to fit them for the purposes of Manure. The great object of the farmer, on the other hand, is so to blend them with the earthy constituents in a proper state of division, as to prevent their too rapid decomposition. Much of this species of Manure is lost in many parts of the country from want of proper attention, or perhaps from ignorance of its value. Animals that have died accidentally, or in consequence of disease, are often suffered to remain exposed to the air, or immersed in water, till they are destroyed by beasts of prey, or entirely decomposed by the action of the atmosphere; and in this case, most of their muscular substance is lost for the land in which they lie, and wasted in the production of noxious gases which pollute the surrounding air. By covering dead animals with five or six times their bulk of soil mixed with one part of lime, and suffering them to remain a few months, their decomposition, as Sir H. Davy remarks, would impregnate the land with soluble matters, so as to render it an excellent manure; and by mixing a little fresh quick-lime with it, at the time of its removal, the disagreeable effluvia would be in a great measure destroyed, and it might be applied with much advantage to any of the stronger species of crops.

Dead animals.

Fish.

Fish forms a powerful Manure in whatever state it may happen to be used; but, however small may be the quantity applied, it cannot be ploughed in too fresh. Herrings have been known to produce a very rank crop of wheat. The refuse pilchards are employed throughout the County of Cornwall with excellent effect. They are usually mixed with sand or soil, and sometimes with sea-weed to prevent them from communicating an excessive luxuriance to the grain. In the fens of Lincolnshire, Cambridgeshire, and Norfolk, the little fish called sticklebacks are caught in the shallow waters in such quantities, that they form a great article of Manure among the neighbouring Agriculturists. It is easy to explain the operation of fish in fertilizing the ground. The skin is principally gelatine, which, from its slight state of cohesion, is readily soluble in water. Fat or oil is always found in fishes, either under the skin or in some of the viscera; while their fibrous matter contains all the essential elements of vegetable substances.

Blubber.

Blubber, an article nearly related to that just described, has been occasionally employed as a Manure. It is most useful when mixed with clay, sand, or any common soil, so as to expose a large surface to the air, the oxygen of which reduces it to soluble matter. It has been known to retain its fertilizing power during a succession of years. The carbon and hydrogen abounding in oily substances fully account for this effect; and their durability is easily explained by a reference to the gradual manner in which they yield to the action of air and water.

Bones.

Bones are now much used as a Manure all over the Kingdom, and especially in the neighbourhood of the Metropolis. After being broken and boiled for grease, they are sold to the farmer. As their effects are more powerful in proportion to the minuteness with which they are divided, the expense of grinding them in a mill would probably be repaid by their increased value; while in the state of powder they might be used in the drill husbandry, and deposited with the seed in the same manner as rape-cake.

Horn.

Horn, regarded as the means of improving the soil, is still more efficacious than bone, as it contains a larger quantity of decomposable matter. The shavings of horn, too, form an excellent Manure, though they are not sufficiently abundant to be in common use. The animal matter in them seems to be of the nature of coagulated albumen, and is slowly rendered soluble by the action of water. The earthy principle in horn, and still more that in bones, prevents the too rapid decomposition of the animal substance, and gives great durability to its effects in strengthening the soil.

Hair, &c.

Hair, *woollen rags*, and *feathers*, which are similar in composition, consist chiefly of a substance resembling albumen united to gelatine. The theory of their operation as Manures refers to the same principles as that of horn and bone. The refuse of the different manufactories of skin and leather,—such as the shavings of the currier, and the offals of the tan-yard and glue-maker,—is found very serviceable to the Agriculturist. Blood, too, as it contains certain quantities of all the elementary ingredients detected in other animal substances, possesses a highly fertilizing quality. The scum taken from the boilers of the sugar-baker, and which is used as Manure, consists principally of bullock's blood, employed for the purpose of separating the impurities of the raw material, by means of its albuminous matter coagulated by the heat. The different species of corals, corallines, and sponges, must be considered as substances of animal origin. They contain a considerable quantity of a matter analogous to coagulated albumen, and might, therefore, be advantageously employed as Manure.

We include under the head of Animal Manures such as are strictly excrementitious, and which, if reference were made to their origin, might be regarded as rather belonging to the class of vegetable substances. Besides the dung collected in stables and cow-houses, great attention is paid in some parts to that produced by sheep. In certain districts on the Continent, these last are kept under cover all the year, for the [illegible] Manure which is thereby created; and when they graze along the sides of roads, young children are employed to collect their droppings. Sheep fed on linseed cake produce an extraordinary fertilizing dung, by which any poor land, whether arable or pasture, may be speedily enriched. A plan has lately been adopted of folding sheep upon straw in the corner of a turnip field, and of carrying their food to them; a method particularly suited for such lands as are too wet and tenacious to have the turnips eaten upon them, or for sloping grounds whence the Manure might be washed down. The dung of birds has likewise been held in high importance by the practical farmer, and especially of those species which live upon fish. This substance is produced in so great quantities upon some small islands in the South Sea, that fifty large vessels are annually employed to convey it to Peru, where it is employed to fertilize the extensive plains in the neighbourhood. The dung of sea-birds has not hitherto been much used as a Manure in this Country; though it is probable that even the soil scraped from such of the small islands on our coast as are much frequented by them, would prove very advantageous. An experiment was made under the superintendence of Sir H. Davy, which was attended with great success.

Night-soil, it is well known, as being very liable to decompose, is a powerful Manure. The disagreeable smell may be obviated by mixing it with quick-lime; for if exposed in fine weather to the atmosphere in thin layers, strewed over with that substance, it soon pulverizes, and in this state may be used in the same manner as rape-cake.

Miscellaneous Manures.

5. Under the head of *Miscellaneous Manures* a great variety of putrescent substances might be arranged, but we shall confine ourselves to a short account of the method of forming composts. All Manures may perhaps be considered as compounds; and hence a reasonable question might arise whether the benefits they afford to vegetation would not be increased, were some of the changes which they undergo when mixed with the soil, previously accomplished by means of Art. This question, which is avowedly of great importance, must depend for its solution on a more perfect knowledge of the process of vegetation itself than we yet possess, as well as of those combinations which are affected by the mutual action of the different substances employed by the husbandman to further its progress. As to composts, it may be remarked, in general, that they are formed of almost every kind of animal and vegetable matter, mixed with earthy and saline ingredients, which being thrown together in considerable masses, undergo a certain degree of fermentation, and thereby promote the decomposition of such of them as happen to have been organized.

Composts, with lime,

It is a general practice to make a compost with a portion of common Manure or lime mixed with a certain quantity of earth from a ploughed field. In this case the two substances are placed in alternate layers in the form of a lengthened heap or mound, which ought to be so covered at top as to prevent the rain from washing through it, and thereby checking the process of fermentation. When the decomposition is completed, the mass should be carefully turned, in order that the ingredients may be perfectly mixed together. The quantity may be increased by collecting weeds or other soluble matter from the ditches and hedges in the neighbourhood, and adding them to the heap before the warmth has entirely subsided. When lime is used, it is customary to lay it down fresh from the kiln in given quantities along the end of a field, and to cover it with four or five times its bulk of pulverized earth, which is immediately beaten down with a shovel to prevent the approach of rain or air. The lime is slaked in a few days by the moisture of the soil, and when any cracks or fissures appear, they ought to be covered up with more earth. After a short period, the two substances are completely incorporated, and the compound may be used for grass or corn-crops, either singly, or together with dung from the stable yard, the consistence of which it materially improves.

with peat-moss.

There is no compost better known in most parts of the Kingdom than that of which peat-moss is the principal ingredient. As this substance consists chiefly of vegetable matter, it constitutes, when entirely decomposed, a very valuable Manure. The best authority on this subject is Lord Meadowbank, one of the Scottish Judges, who about thirty years ago published some important notices respecting the method of preparation, and the soils to which it is most beneficially applied. The peat, of which the compost is to be formed, should be dug out some weeks before it is used, in order that the redundant moisture may evaporate. When carried to a convenient place, it is laid out in two rows, with an intermediate row of dung, which should be so near as to allow a workman to throw them together with his spade. A layer of peat six inches deep and 15 feet wide is first formed. A layer of ten inches of dung next succeeds, then six inches of peat, then four or five of dung, and then six more of peat, and a thin layer of dung. Then cover it with peat all round and above. The height should not exceed 4½ feet, otherwise the weight may be too great, and check the decomposition.

In a medium temperature of the atmosphere, seven cart loads of stable-yard dung, in a fresh state, are esteemed sufficient for twenty-one loads of moss; but in cold weather a larger proportion of dung is required, because more heat is necessary to secure a prosperous result. To every twenty-eight carts of the compost it is beneficial to add one load of ashes, whether from coal, peat, or wood; and when such ashes cannot be procured, half the quantity of slaked lime, well powdered, is a good substitute. By employing the refuse of shambles, six times the quantity of moss may be converted into Manure. A similar proportion is obtained from the dung of pigeons and of domestic fowls.

When the compost is made up, the temperature increases according to the state of the weather and the condition of the ingredients. In Summer the moss is heated in about ten days, but in Winter, if the cold be severe, it requires as many weeks. In the former season there is danger that the temperature shall rise too high and consume the materials. When this is apprehended, a stick should be kept in different parts of the mass, which being occasionally examined will indicate the varying degree of heat. When it exceeds 180° the heap should be watered, or turned over, and cooled by an addition of fresh moss. After the process is completed, the whole appears like a black, rich mould, and has been found, when used either for corn or pasture lands, to be equal to the same bulk of good farm-yard dung. The quantity applied must, of course, be regulated by the nature and condition of the soil; but the farmer will receive an ample remuneration for thirty or thirty-five loads per acre.

It is properly stated by the writer to whom we have referred, that too much attention cannot be given to the preparation of the ground to which this compost is to be applied. It should be clean, dry, well mixed, and friable; for in any other state the Manure does not produce its proper effect. The addition of a small quantity of compost has been known to be attended with a wonderful improvement on a field judiciously fallowed. The texture, colour, and other properties of the soil underwent a very perceptible change for the better; a result which must have been occasioned by the mutual action of the different ingredients in the Manure and land, and the new combinations thence proceeding agreeably to the laws of their chemical affinities. It is obvious that this process must be greatly accelerated by bringing the minute particles of both into contact by an intimate mixture.

Mr C. wright

There is also a compost of peat, lime, and clay, which has been proved to answer well on lands of a certain quality, and more especially for the purpose of raising a plentiful crop of grass. But as we cannot enter into details, we shall finish this section with a short account of some experiments made by the Reverend Mr. Cartwright, with the view of determining the effects of different Manures on the same soil and for the same crop, and particularly of salt used as the means of increasing vegetation. The soil in question was a ferruginous sand, which was brought to a proper consistence by a liberal allowance of pond mud.

In the month of April a portion of the field was laid out in beds, a yard wide and forty yards long. Of these twenty-five were treated as follows:

No. 1. No Manure.
2. Salt, one peck and a quarter.
3. Lime, one bushel.
4. Soot, one peck.
5. Wood ashes, two pecks.
6. Sawdust, three bushels.
7. Malt dust, two pecks.
8. Peat, three bushels.
9. Decayed leaves, three bushels.
10. Fresh dung, three bushels.
11. Chandler's greaves, three pounds.
12. Salt, lime.
13. Salt, lime, sulphuric acid.
14. Salt, lime, peat.
15. Salt, lime, dung.
16. Salt, lime, gypsum, peat.
17. Salt, soot.
18. Salt, wood ashes.
19. Salt, sawdust.
20. Salt, malt dust.
21. Salt, peat.
22. Salt, peat, bone dust.
23. Salt, decayed leaves.
24. Salt, peat ashes.
25. Salt, chandler's greaves.

The quantity of each ingredient was the same as when they were used singly. On the same day one row of potatoes was planted in each bed; and that the experiment might be accurately conducted, the number of sets was the same in all. When the shoots appeared above ground, their comparative excellence was carefully noted. The best row, at that period, was No. 7. from malt dust; and the next best was that from chandler's greaves. The most backward, in the Month of May, was No. 6. which had been manured with sawdust. On the 21st September the potatoes were taken up, when the produce of each row was as follows:

No. 17.	Salt and soot, produced	240
11.	Chandler's greaves	220
18.	Salt, wood ashes	217
16.	Salt, gypsum, peat, lime	199
15.	Salt, lime, dung	198
2.	Salt	195
25.	Salt, greaves	193
4.	Soot	192
10.	Fresh dung	192
20.	Salt, malt dust	189
5.	Wood ashes	187
23.	Salt, decayed leaves	187
24.	Salt, peat ashes	185
7.	Malt-dust	184
14.	Salt, lime, peat	183
19.	Salt, sawdust	180
22.	Salt, peat, bone dust	178
9.	Decayed leaves	175
13.	Salt, lime, sulphuric acid	175
21.	Salt, peat	171
8.	Peat	169
12.	Salt, lime	167
1.	No Manure	157
6.	Sawdust	155
2.	Lime	150

Efficacy of salt

It is remarked by the author of these experiments as a singular circumstance, that of ten different Manures, most of which are of acknowledged efficacy, salt, the effects of which were doubtful, is, with one exception, superior to them all; while in combination with other substances none except chandler's greaves was injured by it. The energy of salt when combined with soot was very striking. But Mr. Cartwright was disposed to ascribe its effects rather to the power which it possesses of attracting moisture from the atmosphere than to any chemical action between the two substances; for the beds on which the salt was used continued visibly moister than the others, even for weeks after its application. Another circumstance noticed is, that the plants which grew on the beds Manured with salt, were of a paler green than the rest, but equally luxuriant; which appearance he at first regarded as an indication of want of vigour, an opinion by no means confirmed by the result. He found, too, that wherever salt was applied, either by itself or in combination with other substances, the roots were perfectly clean.

Experiments with turnips and buck-wheat.

The same gentleman instituted two sets of experiments with turnips and buck-wheat, on a soil so poor as to produce only dwarf heath and lichen. Of 400 grains, 320 consisted of silicious sand, 68 of finely divided matter, and 12 of moisture. Scarcely any calcareous matter appeared. On the 6th of July the beds selected for each set of experiments were respectively sown with turnip and buck-wheat; being numbered and Manured exactly in the same way as in the first set of experiments with potatoes. On the 20th of July Nos. 1, 2. 4, 5, 6. 7. 19, 20, 21, 22. 24. 25. showed little or no marks of vegetation; the remainder were merely in the seed leaf. On the 16th of August four only were alive and in rough leaf, namely,

No. 12. Salt and lime.
13. Salt, lime, and sulphuric acid.
14. Salt, lime, peat.
16. Salt, lime, gypsum, peat.

Results.

These four continued in a sickly state till the middle of September, soon after which they disappeared. The fate of the turnip and buck-wheat was nearly the same; but no certain conclusion could be drawn from these experiments with regard to the effects of salt as a Manure for such crops, for other Manures of undoubted efficacy also failed. The proper inference to be deduced from the whole is, that a certain texture and composition of soil is an essential requisite for promoting the health and vigour of plants, which was abundantly obvious in the greater luxuriance of those plants where the Manure acted in some degree as a substitute for the natural qualities of the land. It has been justly remarked, that these experiments may serve as a model to such Agriculturists as have leisure or inclination to investigate the effects of different kinds of Manure on the crops to which they are applied; and although many of them were made on substances which are procured with difficulty, or are to be had only in small quantities, and cannot therefore come into general use, yet the results obtained were curious and interesting, and, if further examined, might lead to the discovery of some valuable principles as to the constitution and improvement of soils.

Project for employing diluted sulphuric Acid on peat-moss.

While writing this portion of our Essay we have received a faint notice of a scheme for fertilizing peat-moss by means of sulphuric Acid considerably diluted. The project originated somewhere in Germany, whence it was carried into Russia, and reduced to practice it is said with some appearance of success. From the North of Europe it found its way into Ireland, where it has been tried by several Agriculturists, who have experienced much advantage from it in the improvement of their bogs. It has been recently introduced into the Western parts of Scotland, where the soil bears some resemblance to that on the opposite side of St. George's Channel; but the details which have reached us are neither sufficiently ample, nor so accurately described, as to justify any opinion as to its ultimate effects.

Desiderata in Manures.

The farmer and landowner have long had their attention directed to the subject of Manures, as the only source whence any material discovery can be derived to aid their exertions in the production of food. Much has been done by the Mechanic in inventing and improving Agricultural instruments; but the labours of the Chemist have not yet, in any essential point, increased the resources of the husbandman. Manures, generally speaking, are still as bulky, weighty, and expensive as they were fifty years ago; and hence the disheartening fact that they must be used at no great distance from the place at which they are produced, while lands further removed are doomed to continue sterile and unproductive. The desideratum on which practical men have now everywhere fixed their thoughts is the discovery of a substance, so limited in volume and weight as to be easily conveyed from one district to another—an essence, in short, or condensed principle of fertilization, the carriage of which will not, like that of our common Manures, exceed the cost of purchase. It may, perhaps, be found in some one of the Acids or

Alkalis, which in a highly concentrated state might be sent to a distance at small expense; on which account we are the more anxious to become acquainted with the experiments mentioned in the last paragraph, in regard to the fertilizing properties of the oil of vitriol.

Implements of Husbandry.

We have already mentioned the great obligations under which the pursuits of husbandry are placed to the ingenuity of our artisans. The inventions of the Mechanic have not unfrequently anticipated the wants of the Agriculturist; and at this moment, accordingly, all the nations of Europe look to this Country for whatever progress is expected in the formation of new instruments, or in the improvement of the old.

Classification.

Such tools have usually been classed by systematic writers according to their use, or the purposes for which they are employed; and hence they may be arranged as they respect ploughing, sowing, weeding, reaping, and threshing; or, in other words, as they facilitate the rearing of the crop and the preparation of it for the market, in which the interest of the farmer in the produce of his land has its natural termination.

Under the head Agricultural Implements in our *Miscellaneous Division*, we have already described the chief varieties of *Ploughs* and *Harrows*, the *Scarifier*, the *Scuffler*, and the *Roll*.

Machines for sowing.

Various instruments have been used from time to time for sowing corn, and more especially turnips, to supersede the clumsy and wasteful method of scattering the seed with the hand. It is certainly desirable that *every species of seed should be sown in a regular manner and at a proper depth.* In the East Indies machines for that purpose have been employed for Ages; but their introduction into Europe is comparatively speaking of recent date, and is principally to be attributed to the exertions of the celebrated Tull.

Drill machines.

The *Drill machine* for sowing turnip-seed, says Sir John Sinclair, cannot be too much recommended; for it has been the means of bringing the culture of that plant to the highest state of perfection. An excellent instrument for drilling peas and beans likewise has been constructed. In regard to drills for the several sorts of grain, a great diversity of opinion prevails. It seems to be admitted, however, where wheat, barley, or oats are sown in Spring, that, for the purpose of extirpating annual weeds, the drilling system is to be preferred; but in regard to Autumnal or Winter-sown wheat, where the land has been fallowed, the broad-cast system may be advantageously adopted.

Drill-furrow.

Some objections to the practice of drilling corn have been removed by the recent invention of a Drill-furrow, which, though peculiarly well calculated for small farms, might likewise be used with benefit on large ones. It is very simple and may be employed in either of two ways; as a box or barrow attached to the Plough, by which the seed is deposited in the furrow, or in the hands of a boy who follows the Plough for the same purpose. The advantages of this machine are; 1. that the seed being dropped at a proper depth takes a fast hold of the ground, and is not affected by the Winter's frost; 2. the seed may be deposited by means of it in windy weather, when broad-cast sowing would be attended with difficulty; 3. any weeds growing between the rows can be completely extirpated; and 4. there is no way in which clover can be sown with Winter wheat, in the Spring, to greater advantage, as the intervals between the drills can be suitably hoed and the seed laid on a clean bed.

Reaping machine.

But of all the apparatus recommended to the Agriculturist there is not one of greater importance to him than the *Reaping machine*, which however has not yet been brought to such a degree of perfection as to be entitled to general use.

invented Mr. Boyc

The first attempt of this kind is said to have been made by Mr. Boyce, who about thirty years ago obtained a patent for his invention. His instrument was placed in a two-wheeled carriage bearing some resemblance to a cart, but the wheels being fixed upon the axle the latter revolved along with them. A cog-wheel within the carriage turned a smaller one at the upper end of an inclined axis, and at the lower end of this was a larger wheel which gave a rapid motion to a pinion fixed upon a vertical axis in the fore-part of the carriage and rather on one side, so that it went before one of the wheels. The vertical spindle descended to within a few inches of the surface of the ground, and had there a number of scythes fixed upon it horizontally. The machine when wheeled along cut down by the rapid revolution of its scythes a large quantity of corn; but not being provided with any apparatus for gathering it up in parcels and laying it in proper heaps, it proved wholly unfit for the purpose intended.

Improved by Mr. Plucknet,

Mr. Plucknet of London attempted to improve it, but without directing his attention to its main defect. He substituted for the scythes a circular steel plate, made very sharp at the edge, and notched on the upper side like a sickle. This plate operated in the same manner as a very fine toothed saw, and was found to cut the corn much better than the implements of Mr. Boyce. But neither by this method was the principal objection removed.

by Mr. Salmon,

Mr. Salmon of Bedfordshire made a nearer approach than any of his predecessors towards supplying the desideratum so much felt by the Agricultural community. His machine was constructed upon totally different principles, as it cut the corn by means of shears instead of a circular plate; and it was provided besides with a complete apparatus for laying it down in parcels as it was cut.

by Mr. Smith,

But a still more successful effort was made by Mr. Smith, in the County of Perth, who, about twenty years ago, contrived an implement for reaping which might be worked by two men. He afterwards repeatedly enlarged the scale till it required the power of two horses; and at the same time removed an obstacle which applied to the action of his machine on an uneven surface. Suffice it to observe that his cutter is circular and operates horizontally. It is appended to a drum connected with the fore part of the structure, and has its blade projecting some inches beyond the circumference of the lower end of the drum; the machine being so contrived as to communicate, in moving forward, a rapid rotatory motion to this drum and cutter, by which the stalks are cut, and falling upon the drum are carried round and thrown off in regular rows. This ingenious piece of machinery will reap about an acre in the hour, during which period the cutter requires to be three or four times sharpened. The delay occasioned by this necessity might perhaps be obviated on the principle adopted by Mr. Gladstones, who attached to the Plucknet implement a small wooden wheel covered with emery, which being always in contact with the great cutter at the back part, or opposite side to that where the operation of cutting was performed, kept it constantly ground to a sharp edge. The expense of Mr. Smith's invention is estimated at from £25 to £35; and if properly managed it will last for many years, requiring only a new cutter at certain intervals. But notwithstanding the most promising appearances, it is doubtful whether the practical farmer is yet inspired with sufficient confidence in its fitness for all sorts of work, to afford the encouragement necessary to bring it into general use. Fig. 23.

by Mr. Bell.

We have to mention another attempt of this nature made by the Reverend Mr. Bell, a gentleman distinguished for considerable scientific attainments. His machine was tried at Powrie, in the County of Forfar, about three years ago, in cutting down oats, barley, and wheat, on ground of uneven surface and considerable declivity. It takes in a range of about five feet; cutting within three or four inches of the root; and depositing the grain, as it advances, in a very regular manner. It is worked by one horse, and clears about an imperial acre per hour. Its cost may be calculated at nearly £30. In the opinion of a skilful Agriculturist who witnessed the trial of its powers, it is better fitted than any other to supersede the sickle, and thereby to confer a general benefit on the occupiers of land. Fig. 24.

Hainault scythe.

As the process of reaping in our variable climate is attended with many interruptions and much expense, no means have been left untried for facilitating the operation. The *Hainault scythe* had long been recommended as a better implement for this purpose than the sickle or scythe in common use; for which reason two young men were brought over from Flanders under the sanction of the French Consul at Edinburgh, to afford a practical demonstration of the superiority of their instrument, and, at the same time, to instruct the British labourers in the use of it. The trials were made, after public notice in several parts of Scotland, with the different varieties of grain, and under different circumstances as to the state of the crop, as to being light or heavy, standing or laid; and the results are said to have been very much in its favour. The straw was cut nearly as close as with the common scythe, taken up clean, except where the crop was very thin, and laid down regularly in the proper state for binding and threshing. A man with this tool will cut about half an acre a day; and the consequent saving compared with the common sickle has been calculated at fully one third. Fig. 25 and 26.

Horse Rake.

Wherever corn is cut with the scythe the *Horse Rake* is found a useful implement for saving manual labour, as it must also be in the process of making hay. A model was recently brought from America by a gentleman who had visited the United States, and the instrument itself is now generally used in certain districts of Great Britain. The teeth are of iron, 14 or 15 inches in length, and set five or six inches apart from each other; and on the whole, the construction is very simple. A man and horse are said to be able to clear from 20 to 30 acres in a day, disposing the grain in lines across the field, by lifting up the rake and dropping it from the teeth without stopping the horse. We have no doubt that it will be extensively introduced into all parts of the Kingdom as a very useful invention. Fig. 27.

Threshing machine.

Among Agricultural implements no one is entitled to higher commendation for its various uses than that which is employed for *Threshing* and clearing corn. The saving of labour by means of this invention is very great while the work is in all respects better done. Nothing could be more barbarous than the mode adopted by some of the Ancients of separating the grain from the straw, either by burning the latter, or by treading the whole under the feet of oxen. Even the Flail was a very imperfect and fatiguing instrument. Threshing-machines are now common everywhere, and may, it is well known, be worked by horses or water, wind or steam. Water is by far the best power, but as a full supply cannot at all times be had, horses are still employed more generally than any of the other motive energies.

Travelling Shaker.

The essential parts of the machine will be fully understood from an inspection of the engraving. Among the various modifications which are occasionally introduced, one of the most useful is what is called the *Travelling Shaker*, the intention of which is to convey the straw, after it is separated from the corn, to the straw-barn, shaking it completely as it goes along. All well-constructed Threshing-mills have one Winnowing machine which separates the chaff from the corn before it reaches the ground; and a second sometimes receives it from the first, and gives it out in a state nearly ready for market at the rate of six or eight quarters in the hour. If the dimensions of the building do not admit of this last addition, a separate Winnowing machine is sometimes moved by a belt connected with the mill; saving in either case a great amount of manual labour. With a powerful water-mill it cannot be doubted that corn is threshed and dressed for the market at an expense not exceeding that which was incurred by the old process for threshing alone. The great advantage, too, of transferring forty or fifty quarters of grain in a few hours, and under the eye of the master, from the yard to the granary, is of itself sufficient to recommend this invaluable machine, even though it were not also more economical. Fig. 28.

The author of the *Treatise on Rural Affairs* has furnished the following estimate of the profit that might be derived by the Public were Threshing-mills universally adopted. He calculates,

1. The number of acres producing grain in Britain at.................. 8,000,000
2. The average produce in quarters at three per acre................ 24,000,000
3. The increased quantity of grain obtained by Threshing-mills, compared with the Flail, at one-twentieth of the whole, or in quarters at... 1,200,000
4. The value of that increased quantity at forty shillings per quarter.... 2,400,000
5. The saving in expense of labour at one shilling per quarter........ 1,200,000
6. The total profit *per annum*, if all were threshed by machinery, at.. 3,600,000
7. The actual profit *per annum*, on the supposition that only half of the grain produced were threshed by machines, at................ 1,800,000

Miscellaneous Implements.

In addition to the implements already described we might mention the *Chaff-cutter*, the *Turnip-slicer*, the *Steaming apparatus for preparing the food of cattle*, and a *Machine for bruising the corn which is given to horses.* This lost is of greater value than it is usually imagined, as many horses are known to swallow their *oats* without complete mastication, while others which have lost their teeth derive much advantage from this artifical assistance. We must pass over with a similar brevity the various descriptions of wheel-carriages which are used on farms, from the Irish car to the Gloucestershire waggon. There are besides various mechanical inventions used for harvesting corn, and depositing it safely in the barn yard. Sir J. Sinclair holds the opinion that stacks are greatly preferable to barns, more especially since the plan has been adopted of placing the former on stone or cast-iron pillars, by which the corn is kept perfectly dry, and the ravages of vermin are prevented. In some districts, if the season be wet, stacks have *bosses* placed in the centre, consisting of a triangle of wood, through which the air has freedom to circulate nearly to the top of the stack. If the grain has not been quite dry, it gains much advantage from this simple expedient. Fig. 29.

Bosses for corn stacks

On Tillage.

Having examined the constitution of soils, the modes of draining and irrigation, the various kinds of manure, and the principal implements which are used in husbandry, we are now prepared to accompany the farmer in the more practical branches of his profession, and to record his progress in the culture of his fields and the growing of his crops. It is, indeed, customary before proceeding to the actual processes of ploughing, sowing, and reaping, to make a series of observations on the different plans which have been adopted in the Agricultural districts of the Kingdom, for dividing fields and erecting fences. To this is not unfrequently added a dissertation on rural establishments, comprehending a view of the several buildings which may be thought necessary to accommodate the tenant, his servants, his cattle, as well as his pigs and poultry, and, at the same time, supply the means of protecting his crop, his corn, potatoes, turnips, and hay, from the effects of rain and frost. We abstain from such details, not only because our plan is inconsistent with excessive minuteness, but more especially because there is no fixed rule which could be made to apply to any number of contiguous farms, much less to the whole country. The fences which are found most suitable in Devonshire would not answer in Cumberland; and the style of house which affords the greatest comfort in Caithness, would be rejected on the banks of the Severn and the Thames, as inconvenient and devoid of elegance.

Turning up the soil.

Fittest season.

The first step is to turn up the soil and prepare it for the reception of the seed. But before the operation of the plough begins, it is of no small importance to consider the nature of the land, the season of the year, and the species of crop which it is proposed to raise. It is a general opinion that there are few soils which are not improved by being turned up about the end of Autumn or beginning of Winter, as it is understood that they thereby absorb a great quantity of moisture to meet the demands of the following Summer; whereas, if they are not ploughed till the Spring, the rapid evaporation which ensues occasions a deficiency of one of the essential elements of vegetable life. It is supposed, too, that the furrow exposed during the cold season becomes mellow, and derives, moreover, some beneficial influence from the atmosphere; an opinion which may be traced back to the days of Virgil, and perhaps to an epoch still more ancient. But the experience of modern times does not altogether confirm the judgment of the Greeks and Romans in this particular point. The principal benefit of Autumnal ploughing is confined to strong adhesive soils, which by means of the frost acting on the redundant moisture, unquestionably renders them more friable, and, of course, fitter for the reception of all kinds of seed.

Ground n to be ploughed when we

It ought to be especially observed that no land, whatever may be its qualities, should be ploughed in a state of wetness. Tenacious soils, when subjected to the operation of ploughing in such a condition, are apt to run together into lumps, which it is afterwards extremely difficult to reduce; besides being greatly injured by the treading of the cattle, whose feet make holes which become filled with putrid water. This observation applies chiefly to marshy fields, which have been recently brought into cultivation, and which, above all others, ought not to be endangered by an unseasonable renewal of Tillage.

Dimensi of the fu row

In highly improved districts, great attention is paid to the dimensions of the furrow, and the angle at which it is made to rest. When the breadth and depth are nearly equal, it turns over very naturally at an angle of forty-five degrees; but when the breadth much exceeds the depth, it falls over in nearly a flat position, each successive one overlapping a little the preceding. The nature and condition of the land determine the preference to be given to each of these modes of ploughing. The square slice is considered best adapted for laying up stubble land after harvest, to be exposed during the Winter as a preparation for fallow or turnips. The shallow slice with considerable breadth is convenient for breaking up old pastures, because while it conceals the grassy turf, the fertile soil is not buried too deep. No wise farmer approves that style of aration which makes the depth of the furrow slice exceed the breadth.

Considera tions by which the are determined.

Generally speaking, in determining the depth of the furrow, the quality of the soil, and the kind of crop to be raised, must be attentively considered. Some shallow soils are extremely fertile, but rest on a substratum which is extremely injurious to vegetation. In such cases, deep ploughing would be highly improper; but, on the other hand, when subsoil contains ingredients, such as calcareous and soluble matter, which serve to increase its productive qualities, it may be useful to the crop to have a portion of them occasionally turned up by the plough. Mr. Young recommends that one deep ploughing should be given every second year; after which, he maintains, that a mere stirring of the surface answers better than very deep working. Even for the purposes of cleaning, it is found that an ebb furrow, followed by regular hand-hoeing is much more effectual than any attempt to bury the weeds.

Deep ploughin where necessary.

For certain crops, indeed, such as carrots and parsnips, deep ploughing is indispensably requisite. In soils which can admit of it, *trench-ploughing* is found advantageous; a process which is accomplished by one plough following another in the same furrow, and the second throwing its slice on the top of that which has been turned over by the first. In this way the land is completely moved to the depth of twelve or thirteen inches.

Ridges.

Their dire tion

In ploughing a field some attention ought to be paid to the breadth of the ridges, or the distance of the water-furrows from each other; for upon this arrangement depends not only the proper draining of the surface, but also the regular application of manure, the equal distribution of the seed, the weeding, reaping, and other branches of manual labour. It is likewise recommended by experienced farmers that as far as the situation of a field will admit of it, the direction of the ridges should be North and South. Deviations from this rule, for the purpose of drainage, or on account of the particular form of an inclosure, may be sometimes necessary. But it seems always advantageous to bring the course of the ridges as near as possible to the line abovementioned; for it appears that in those which have an East and Westerly direction, even when the elevation is not considerable, the crop on the South side has ripened a week earlier than that on the North.

and breadth.

Great diversity of opinion prevails as to the proper breadth of ridges; a point which, it is manifest, depends altogether on the qualities of the soil. Where the land is of a light sandy nature, the ridges may with perfect safety be made both flat and broad; whereas on a stiff clay, they should be more narrow as well as higher and of a rounded form, that the redundant moisture may be discharged. On some such soils a ridge of three or four feet is considered sufficiently wide; and in Essex, especially, this method is found to yield better crops than when the water-furrows are placed at more distant intervals. But as we have already suggested, there is no uniformity in this particular, the practice being regulated in every County by the properties which distinguish the various farms, as also by the uses to which the land is applied.

Fallowing.

There is no subject connected with Agriculture on which there has been a greater change of practice as well as of theory, than the ancient usage of Fallowing. A vague notion seems to have prevailed in all the Countries of Europe that the exhausted soil required some time for repose, in order to recover its wasted fertility. At the present day many authors maintain that, under good management, and a proper succession of crops, it is hardly ever necessary for most kinds of land; while others with equal confidence assert, that Summer Fallowing forms an essential part of a system of good husbandry, and that on certain soils it is altogether indispensable. The avowed object of this process is, to clear the ground from weeds, and to reduce it to that consistence which is necessary to healthy vegetation. The more zealous advocates of the practice admit, though with reluctance, that it may be restricted to clay soils, and to those which are of a tenacious quality; such being apt to retain a superabundance of moisture, and to be thereby rendered very often unfit for receiving cultivation at the usual season. Ploughing in Summer, they remind us, reduces the hardened mould to the degree of friability and minuteness of division which are essential to the concoction of the manure, to the approach of the genial atmospheric influences, and to the ready nourishment of the plants. The soil from being brought repeatedly in contact with the air is supplied with a larger proportion of oxygen, which uniting with the carbonaceous matter deposited by the husbandman, produces an acid extremely beneficial to all the vegetable tribes. According to the same hypothetical reasoning, the water which is absorbed by the pulverized field is decomposed, and its hydrogen combining with the azote of the air forms ammonia, while another portion of oxygen uniting with part of the nitrogen furnishes one of the ingredients of potash, and thereby contributes greatly to the improvement of the land. Certain vicissitudes of temperature, too, which, no doubt, take place wherever any decomposition or Chemical change in the constituent parts of bodies is effected, are also supposed to be useful, either directly or indirectly, in promoting the growth of plants.

Sir H. Davy's objections to Fallowing.

But as Sir H. Davy observes, there is some reason to suspect that the benefits derived from Fallowing have been greatly overrated; and although it may be admitted as necessary in lands much infested with weeds, and particularly on such as cannot be pared and burned with advantage, it must nevertheless, on the whole, be pronounced unprofitable as a part of general husbandry. He rejects the doctrine that certain principles necessary to fertility are derived from the atmosphere, and supplied to the pulverized soil, during its repose and repeated exposure to the air; as well as the old opinion as to the effects of nitrous salts on vegetation. By the decomposition of the weeds buried under the furrow a certain quantity of soluble matter is no doubt furnished to the land; but it may be questioned whether the portion of useful manure in a field at the end of a clear fallow, is equal to what it contained when the operation commenced. By the action of the vegetable matter on the oxygen of the atmosphere carbonic Acid gas is formed; but the greater part of it is dissipated and lost to the farmer. The rapidity of the decomposition of the soluble substances contained in the soil is greatly promoted, and the volatile fluids are exhaled by the influence of the Sun; but at the very time when a large quantity of nutritious matter is produced there are no useful plants to derive any benefit from it.

His general remarks.

The whole theory of Fallowing, if we omit the mere eradication of weeds, rests on the principle that land, while not employed in raising a regular crop, may be so treated as to supply food for itself, or, in other words, to improve its productive qualities. This object, as we have elsewhere stated, may be in a great measure accomplished by means of succulent vegetables grown for the purpose of being ploughed down. But during a Summer fallow, properly so called, no crop is produced either for food to animals or for the nourishment of the soil itself. Even the texture of the furrow is less improved than during its exposure in Winter, when the freezing of the moisture it contains has the effect of reducing it to a gentle condition. Besides, since the drill-husbandry has been introduced the land is kept free from weeds by hand-hoeing, and manure is supplied either by the green crops themselves, or from the dung of the animals which feed upon them. It is the peculiar advantage of the convertible system of cultivation that the whole of the manure is employed; those parts of it which are less fitted for one crop being suitable for the nourishment of another. Thus the quantity applied to turnips affords a sufficient portion of soluble matter not only for their growth, but also for that of the barley which follows in the regular succession of modern husbandry. Nay the grass-seeds derive from the same supply an abundant source of luxuriance, while the rye-grass and clover remain, which draw a very small part of their organized matter from the soil, or only consume the gypsum, a mineral ingredient of little use to other plants. These grasses are supposed to receive a large portion of their nourishment from the atmosphere, and their roots and leaves when ploughed down at the end of two years, supply a pabulum to the succeeding wheat crop. At this stage of the course the farm-yard manure, which contains phosphate of lime and other matters of difficult solubility, is fully decomposed; and as soon as the most exhausting crop is raised the application of similar substances is repeated.

Mr.Gregg's system.

These remarks were suggested to Sir H. Davy by considering Mr. Coke's plan of cultivation independent of Summer Fallowing. Mr. Gregg, whose ingenious system was published by the Board of Agriculture, had the merit of first adopting a similar plan on strong clays. He allows the ground after barley to remain two years in grass; then sows peas and beans; afterwards ploughs in the stubble of these crops for wheat; and, in some instances, fallows the wheat by a course of Winter tares and barley, which is cut in the Spring before the land is sowed with turnips.

Mr. Middleton's observations.

There can be no doubt that were it possible to devise any method of cropping by which the produce, fertility, and good condition of the soil could be maintained without the intervention of a Summer Fallow, the saving would be very great. Mr. Middleton accordingly, in his *Report of the State of Agriculture in Middlesex*, when speaking of the advantages to be gained by a proper succession of crops, very justly remarks, that the "benefits to be derived from this measure are not to be estimated. Among the first of these will stand the abolition of Fallows, and the introduction of green crops to supply their place, over an extent of about three millions of acres of arable land which have hitherto, under the Fallow system, produced nothing during the Fallow year. So far as tares and turnips, or potatoes and peas, or turnips and potatoes, or any two good crops can be raised in one year, in place of a Fallow, the produce will be double in quantity what it has been under the former system. There are about nine millions of acres in England and Wales in the course of two crops and a Fallow; that is, six in crop and three in Fallow; from which it appears that by procuring one crop in place of the Fallow, one half more is added to the former produce."

Fallows disused in the Netherlands,

According to a statement made by Sir John Sinclair, in his *Hints on the Agricultural State of the Netherlands*, Fallows are more rarely practised in Flanders than formerly, and in some districts are entirely abolished. The succession of crops on strong lands in the neighbourhood of Bruges is the following; Fallow, winter barley, beans, wheat, oats: sometimes there is a Fallow every fourth year, and sometimes wheat and Fallow alternate. But in the Plain of Fleurus, in the Walloon Country, Fallows are now rarely seen. At one period they were enforced by a clause in the leases as an indispensable part of husbandry in that fertile district. M. Mondez, who was well acquainted with Flemish farming, when he entered on the possession of grounds near the town just named, having stipulated with his landlord that he should be at liberty to pursue a different plan of cultivation, took the lead in this great improvement; and for a period of forty years he seldom had occasion to practise Summer Fallow. He superseded the old method by introducing a judicious rotation of crops. The culture of beans, for example, is successfully practised in other parts instead of a Fallow. This crop is succeeded by an abundant one of wheat or Winter barley; and it is added by Sir John, "that this system merits to be encouraged for the great advantage derived from it; for without any additional manure, which however it tends to furnish, it retains the fields in as high a state of fertility as can be done by the Fallow system; it exacts but a moderate degree of attention, and it requires neither any extraordinary expense nor hazardous combinations."

The same author informs us, that it is now a maxim in the Plain of Fleurus that, wherever it is possible to manure the land fully every ninth year, Fallows are perfectly unnecessary; and he notices a Paper on this subject by M. Burtin of Brussels, who recommends mixing sand with the soil, to alter and improve its texture, and burning clay in large masses for the same purpose, as a substitute for Summer ploughing. At one time, we may remark, Fallowing was so much practised in Swisserland that it alternated with every crop; but at present it is almost entirely given up, the necessity for it being precluded by the following rotation, wheat, carrots, vetches, barley, potatoes.

and in Swisserland.

Norfolk Bastard summer till.

In Norfolk a kind of Fallow, denominated by the farmers a *Bastard summer till*, is occasionally practised. If it shall appear that a piece of ground from which clover or some other cultivated grass has been cut, is not sufficiently clear for the reception of the following wheat crop, it is ploughed two or three times, if it can be accomplished, before harvest; and, when it is necessary, the assiduous application of the roller and harrows is not neglected. For the purpose of clearing pea-stubble, it is also subjected to a similar operation. When the crop is removed from the land, the straw is harrowed up, collected, and carried away. A single ploughing is then given; after which the ground remains in that state till the conclusion of the harvest, when it receives two cross ploughings, and finally, a fourth as a preparation for the seed.

Drill sowing.

Introduced by Mr. Tull.

His mistakes.

As the improvement now mentioned has arisen chiefly from the introduction of green crops cultivated on the plan of what is called the *Drill Husbandry*, we shall make a few observations on its history and advantages. It has been already stated, that this method was introduced into Britain by Mr. Jethro Tull, a gentleman in Berkshire, who applied it to his own property about the year 1713. Struck with the remarkable effects which the new mode produced, and ascribing the abundant crops which he obtained to the perfect culture thereby accomplished, rather than to the fertilizing qualities of the manure, he extolled the discovery beyond all bounds. He described it as calculated to supersede the necessity of manure altogether, the application of which he viewed as a waste of time, labour, and expense. By thus overrating the advantages of Drilling, and loading it with erroneous views on points not necessarily connected with it, there is reason to believe that he retarded the progress of his favourite system. In the present day when the utility of manure is so well understood, there is no danger that any one will be misled by the opinions of Mr. Tull; and we enjoy accordingly all the benefit of his practice without incurring the hazard of his hypothetical conclusions. It required the enthusiasm of an inventor to warm the head to such an extent as to induce a practical Agriculturist to overlook the necessity of recruiting the energies of the soil, or to imagine that the best directed labour would ever supersede the application of manure.

Advantages.

The main advantages derived from the practice of Drilling are understood to be, a saving of seed; a more regular and certain growth, from the seed being more regularly deposited; a more abundant crop and of a better quality; the more easy and effectual destruction of weeds; harvesting the crop at less expense and in a cleaner state; and the more perfect cultivation of the soil by means whereof it is left in a better condition for the next sowing. The objections to it apply not to the

Objections.

process itself but to the difficulty of having it well performed, and the bad effects which result from awkward workmanship. But the experiments made by Mr. Amos, detailed at length in his *Treatise on Drill Husbandry*, have removed all doubt as to the superior excellence of this method. His investigations were made on different soils; and in all of them, two acres of land, laid up in ridges of eleven feet broad, were sown alternately broadcast, and with the Drill machine. We may state one or two of the results; observing that the sum placed opposite to the name of the crop denotes the superior value of that which was Drilled compared with the produce of the broad-cast.

Mr. Amos's experiments.

	£.	s.	d.
Oats on stiff loam	1	3	0
Coleseed after the oats	0	1	0
Barley after the coleseed	1	5	3
Beans after the barley	1	1	3
Wheat after the beans	1	14	5
Turnips on sandy loam	0	8	9
Barley after the turnips	0	17	10
Red clover after the barley	0	10	6
Wheat after the red clover	1	9	9
Potatoes on sandy loam, part hand-hoed, and part horse-hoed, in favour of the latter	3	13	10
Barley after the potatoes	1	16	2
Red clover after the barley	0	13	6
Wheat after the red clover	1	16	0
Cabbages on stiff loam, part hand-hoed and part horse-hoed, in favour of the latter	2	10	9

We ourselves have witnessed experiments on the comparative advantages of Drilling and broad-cast, in regard particularly to wheat and oats; and the result in all cases has tended to prove the decided superiority of the former. Not only is the quantity greater, but the quality is considerably better; and if the season has been wet or otherwise unfavourable, the latter point of improvement is still more manifest. It deserves to be remarked, however, that the saving of seed is quite illusory, for the best farmers bestow as much on the land in the form of Drilling as when it is scattered from the hand. Nor ought it to escape attention that a good deal depends on the distance between the rows or Drills; a branch of the subject which has been well illustrated by Mr. Young, though his conclusions are not entitled to the authority they would have possessed had all the experiments been performed on the same soil and under the same management. Mr. Tull, it is well known, recommended the Drilling of wheat, barley, and other corn crops, at the distance of three, four, and even five feet between the rows; but as this part of his practice was connected with the hypothesis that a well-directed culture might supersede all other means of fertilizing land, he has not been followed, except by a few individuals who were determined to adopt his whole system, and attempt to produce plentiful harvests without the aid of manure. It is obvious that the number of rows in a given space should be regulated by the nature of the soil and the species of the plants; strong land requiring more room for its rank vegetation, and that which is lighter admitting the Drills at a smaller distance from one another. From ten to fourteen inches is recommended as a sufficient interval for rows of corn where the field is in good condition; but in cases where a luxuriant crop is not to be expected, the distance may be reduced with advantage to the narrower limits of eight inches.

No saving in seed.

Intervals between Drills.

Method of Drilling.

The process of Drilling, or the deposition of seed in rows by means of a machine, requires considerable care in the performance. The points which demand particular attention are the keeping the rows straight and at equal distances throughout their whole length, the dropping the seed at a proper depth, and the delivering it in proper quantity according to its kind and the nature of the soil. For these purposes the ground must have been previously well prepared by repeated ploughing and harrowing, except in the special case of Drilling beans with one furrow. This operation is generally performed in the course of ploughing, either by a person pushing forward a Drill barrow, or by attaching a hopper and wheel with the necessary apparatus to the plough itself. The mode of regulating the depth of the Drill, and the quantity of seed delivered, must depend on the kind of Drill used, and only requires attention in the holder. In Drilling turnips the land is most commonly made up into ridgelets, at the distance of twenty-seven or thirty inches from centre to centre, formed by a single *bout*, or double motion, of the common plough. The Northumberland machine, which sows two rows at once, is then drawn over them by one horse walking between the ridges without a driver; the holder at once performing that office and keeping the instrument steady on the top of the Drills, or ridgelets, as they are sometimes called. One of the two rollers smooths the surface before the seed is deposited, and the other follows to cover it and compress the soil. In Drilling corn, several rows are sown at once, and great care is requisite to keep the machine steady and in a straight line. If only five rows are done at once, the work may be performed with one horse and a ploughman, but if the implement is so large as to cover nine or ten rows, there must be two horses in the yoke, and guided by a driver.

Northumberland Drill machine.

For the Northumberland Drilling machine, we refer to fig. 30. The roller *a* which goes before the seed has two concavities, and thus leaves the ridgelets in the very best form for receiving it; after it is sown, two light rollers, *b b*, follow and cover it.

Morton's Drill machine.

Of corn-drills, Morton's *improved grain Drill machine* is undoubtedly the best and simplest. In it three hoppers are included in one box, the seed escaping out of all the three by the revolution of three cylinders upon one axle; and Drills of different breadths are produced by the simple shifting of a nut that fixes a screw moving in a groove in the under frame, by which the distance between the two outside conductors and the central one (which is fixed) can be varied from nine to eleven inches. And in order that the two small wheels may be always at the same distances respectively as the conductors, there are two washers, or hollow cylinders, an inch in breadth, in the axle arms of each, which may be transferred either to the outside or inside of the wheels, so as to make this distance from the outside conductors, nine, ten, or eleven inches respectively. The small wheels may be raised or depressed, so as to alter the depth at which the seed shall be deposited, by the action of a wedge which retains the upright part of the axle in any one of a number of notches, which are made similarly in both, and which are caught by an iron plate on the upper side of the arms which carry the axle. This machine, says Mr. Loudon, may be still further improved by increasing the number of conductors from three to five, an improvement, we may add, which has already taken place. Fig. 31.

System of Cropping

Modes of classification.

The great variety of soil and climate in this Country suggests and even renders necessary a considerable difference in the kind of crops that must be raised by the farmer, who, in this important matter, is frequently deprived of all power of choice. In a systematic point of view, the produce of land may be considered under such several heads as shall happen to suit the object of the writer; the main distinction being founded on its uses and application, as food for Man, or for the lower animals: the former class comprehends the various species of corn, wheat, barley, rye, oats, peas, and beans; while the latter may be extended to all the vegetable tribes which fall under the denomination of green crops. It is manifest, however, that this distribution does not rest on any fixed principle, because there is none of the *cerealia*, or genera of grasses, from which the human being derives his subsistence, which may not be applied with equal success to the tenants of the stable, the cow-house, and the fold. Perhaps a clearer distinction might be founded on the property of being culmiferous or otherwise, thus dividing the products of land into such as are cultivated for their seeds, and such as are cultivated for their leaves; but as our object is to meet the convenience of the common reader, rather than to comply with the requisitions of a theory not well established, we shall proceed to give an account of those crops which chiefly occupy the attention of the British Agriculturist, and supply the ordinary demand of our markets.

Wheat.

Of these *Wheat* deservedly occupies the first place, as being in these Islands the main stuff of bread. It is universally admitted that the soils most suitable for this species of grain are those of a strong, loamy, and even clayey description; but it is not denied, at the same time, that where manure can be had in abundance, and the climate is not altogether unfavourable, Wheat may be raised successfully on lands of a much lighter nature. As far as our own experience goes, we should say that not less depends on the subsoil than on the qualities of the pulverized portion which is turned up by the plough; for as the fibres descend to a great depth in search of nutriment, the plants sustain a serious injury from contact with ferruginous ingredients, in the subjacent strata. Before the introduction of turnips and clover, all lands not decidedly cohesive were thought quite unfit for Wheat; but it is one of the many advantages arising from the use of green crops that new powers have been thereby added to the soil, and its capabilities enlarged.

Sowing.

Till a very recent period, Wheat was hardly ever sown but after a regular summer fallow; a method which is openly condemned by Mr. Young, in his *Calendar of Agriculture.* "If," says he, "there be one practice in husbandry proved by modern experience, to be worse than another, it is that of sowing Wheat in fallows. If fallows be thought necessary, let them be sown with barley, or oats, or any thing but Wheat. But Wheat may be advantageously cultivated after clover, tares, peas, beans, turnips, potatoes, and similar crops, regulating the succession according to the nature of the soil and the condition of the land." Beans which have been under suitable culture, are considered by him as the best preparation for Wheat; clover and tares being the next in order regarded as preparatory sowings. But whether Wheat be sown in fallow, or whatever may be the preceding crop, it is scarcely necessary to observe that the land should be in a friable and pulverized state, and completely cleared of weeds. When Wheat succeeds beans, the state of the weather will seldom permit more than one ploughing; for which reason, before this be attempted, the operation of cross-harrowing is strongly recommended, as well for the purpose of levelling the rows, as for clearing the surface from cumbersome weeds and straw. To preserve the crop from the effects of moisture, during the Winter, the ridges should be gathered up or raised in the middle, and the open furrows on each side be kept free from obstructions. When Wheat is sown after clover, a still greater degree of attention to the process of ploughing becomes necessary, in order that the grass roots may be completely covered; for when this part of the work is carelessly executed, the remaining stems vegetate and send up shoots, to the material injury of the young plants.

Varieties.

But the cares of the farmer are not confined to the cultivation of the fields meant for Wheat. He must exercise a similar vigilance and discernment in the selection of the seed; and this not only as it respects the quality of the grain, but the kind or species which may be proved most answerable to his soil and climate, which every day of the year either aid or oppose his exertions. The varieties of this grain are too numerous to be specified here; but the most general distinction is that which respects colour, the red and the white comprehending the intermediate shades. Wheats are again divided into Summer and Winter varieties; the former being usually bearded, while the latter sometimes shows a woolly ear and a very thick chaff. The white description affords flour of a finer quality than the red; but this disadvantage, in the case of the latter, is compensated by the property it possesses of coming more early to the sickle, and of growing on an inferior order of soils under a less genial sun. Summer Wheat has been long cultivated in some parts of England, particularly in Lincolnshire, and might probably be found to succeed in the more Southern Counties; but in Scotland it has not obtained any preference, even when used for a crop sown in Spring.

Pickling and steeping.

As Wheat-seed is sometimes prepared with pickles, or steeps and quick-lime, as a preventive of smut, we shall give a short account of a method which is followed in some districts with considerable success. Take four vessels, two smaller and two larger, the former with wire bottoms and of a size to contain about a bushel, the latter sufficiently capacious to contain the others within them. Fill one of the large tubs with water, and putting the Wheat in one of the smaller, immerse it in the water, stirring and skimming off the grains which float above, and renew the water as often as necessary till it comes off quite clean. Then raise the small vessel in which the Wheat is contained, and repeat the process with it in the other large tub which is to be filled with stale urine; and in the mean time wash more Wheat in the water tub. When abundance of water is at hand, this operation is by no means tedious; and the Wheat is much more effectually cleansed from all impurities, and freed more completely from all weak and unhealthy grains than can be accomplished by the winnowing machine. When thoroughly washed and skimmed, let it drain a little, then empty it on a clean floor, and riddle quick-lime upon it, turning it over and mixing it with a shovel, till it be sufficiently dry for sowing.

M. Prevost's experiments.

Blue vitriol.

The experiments of M. Prevost quoted by Sir John Sinclair, in a Work formerly mentioned, show in a striking light the advantage of previous preparation of the seed for the prevention of smut. The following were the results: 1. infected grain, without any preparation, had one-third of the crop smutted; 2. infected wheat, simply scalded, gave one-fifth smutted; 3. sound wheat, without any preservative, had one-fifth part infected; 4. infected wheat well moistened in a solution of blue vitriol, or sulphate of copper, in the proportion of nearly two ounces for three bushels of wheat, had only one-hundredth part affected with smut; 5. infected wheat, well moistened with a solution of the same kind, in the proportion of about four ounces and a half of blue vitriol to three bushels of wheat, gave only one three-hundredth part smutted. This solution is described as being equally efficacious in preventing mildew. The process may be more particularly detailed in these words: take three ounces and two drams of blue vitriol, and dissolve it in four gallons of cold water, the proportion allowed for every three bushels of the wheat to be prepared. Into another vessel capable of containing sixty or seventy gallons, throw from three to four bushels of wheat, and pour upon it the prepared liquid, till it rises five or six inches above the corn; stir it well, and remove the light grain from the surface. The wheat after being half an hour in the solution, is thrown into a basket to allow the liquid to drain off. The seed is then washed with pure water, and well dried before sowing. It is said that it may be kept after this process quite sound for several months. A similar application of blue vitriol is practised by Mr. Butler of Derbyshire. He dissolves two pounds of it in as much urine as will moisten twelve bushels of wheat, and after it has floated a sufficient time it is dried with quick-lime.

Kiln-drying.

Rolling.

Another preventive of smut recommended to the practical Agriculturist is kiln-drying; an expedient, however, which must be adopted with great care, as the slightest excess of heat might destroy the powers of vegetation. A practice has likewise been introduced by some farmers of passing their seed wheat through rollers, by which means a black powdery matter is separated from the surface of the grain. This also is a method which, however successful it may have proved in judicious hands, must not be hastily imitated, there being a manifest hazard that part of the corn shall be lacerated, or otherwise injured.

Quantity of seed.

No fixed rule can be laid down as to the quantity of seed which ought to be given to an acre of land suitably prepared for wheat; because this is a point of practice which must be determined in every case by a reference to the fertility of the soil, the nature of the climate, and even the period of sowing. On a rich field brought by culture to a good condition and sown early, the quantity need not exceed two bushels. In no instance should it pass three bushels per acre; although on bean-stubble the allowance should certainly be more liberal than on fallow or after a green crop.

Modes of sowing.

Ribbing.

Dibbling.

In regard to the particular modes of sowing, we have already said all that appears necessary. Our reasons for preferring the drill-system to the more ancient method of broad-cast are founded on experiment and long observation; and wherever the land will admit of it, the farmer will find the expense of labour and machinery amply repaid. The method of *ribbing*, as it is called, or the making of small furrows at the distance of nine or ten inches, answers nearly the same end as drilling. The seed, it is true, is scattered by the hand in the usual broad-cast manner, but as it necessarily fall, for the most part in the furrows, the crop rises in parallel rows, and the ground is levelled by harrowing. This plan has nearly all the advantages of the other, so far as respects the rays of the sun and the circulation of air among the plants; but as some shoots will unavoidably spring up between the lines, it is not so well fitted for the operations of clearing, weeding, and hoeing. In the County of Norfolk, the Dibbling of wheat is still practised to a considerable extent; though we do not find that it is attended with any advantage except the sowing of seed. An expert dibbler, with the assistance of three children to drop the grains, sows about two roods a day; the quantity expended being from four to six pecks per acre, proving a gain on that article to the amount of nearly a bushel on four roods. Some attempts have been made to introduce machinery for this purpose, but hitherto without success.

Hoeing.

Multiplication of stems.

After the usual operations of culture and sowing, the anxiety of the farmer is confined to the two essential points of keeping the field free from weeds and superabundant moisture. No water should ever be allowed to stagnate on the surface of the ridges, or even in the open furrows, otherwise the seed rots and perishes, or if it escape total destruction, it sends forth sickly plants which never come to perfection. Where the broad-cast method of sowing is continued, the process of clearing cannot be fully accomplished; being confined to such weeds as can be removed by the hand. But wherever wheat is drilled, the business of hoeing can be effectually executed; a species of labour which is not less beneficial to the crop by stirring the soil and closing it in the roots, than by eradicating the intrusive vegetation by which it would soon be encumbered. It has been ascertained that by loosening the earth and gathering it round the stems of plants, *tillering*, or the production of new stalks is greatly promoted, and particularly in the drill-husbandry. Some curious facts are recorded of the wonderful multiplication of stems effected by this process. In a moderately good crop of drilled wheat, Sir H. Davy counted from 40 to 120 stalks springing from a single grain; and he quotes Sir Kenelm Digby who saw in the possession of the Fathers of the Christian Doctrine at Paris a plant of barley which they preserved, and which consisted of 249 stalks from one seed, and yielded 18,000 grains. He refers also to Mr. Miller of Cambridge, who sowed some wheat on the 2d of June, and on the 8th of August a plant was taken up, separated into eighteen parts, and replanted. In September and October, they were again taken up, and divided into sixty-seven separate parts, to remain during the Winter; and in March and April they were also taken up, when they produced 500 plants. The number of ears from a single grain amounted to 25,509, and the grains were estimated at the amazing number of 576,840. The produce weighed nearly forty-eight pounds, and measured three pecks and three-quarters of a peck.

Feeding down.

In some districts we have observed the practice of turning in cattle into a field of wheat, *to feed it down*, when it appeared too luxuriant at an early part of the season. Some benefit was supposed to be derived from the removal of the upright stems by which the growth of the lateral shoots become more vigorous; but if this practice be ever useful, it must be confined to cases of excessive luxuriance, and where the land is of a firm texture. In short, it can only be regarded as a hazardous alternative, resorted to when the crop would otherwise be certainly lost.

Diseases smut.

The principal diseases to which wheat is exposed are the *smut* and *mildew*. The former appears in the shape of a black ball, which occupies part of the ear, and thereby not only so far diminishes the produce, but contaminates, more or less, all the sound grain, rendering it unwholesome food, and quite unsuitable for seed. A remedy has been already suggested for this evil, as it is understood by all intelligent Agriculturists to be perpetuated by means of propagation, or, in other words, that diseased corn is always reproduced in an unhealthy state. But a more certain preventive will be secured by the resolution never to sow wheat which has been even in the slightest degree tainted with smut.

Mildew.

The ravages of *mildew*, in particular cases, are even more destructive than that of the pernicious blight just mentioned. It is generally imagined to originate in a disordered state of the atmosphere; and when it takes place between the periods of flowering and ripening it has been known to lay waste whole fields in the course of a week. Nor have any means been discovered for putting a stop to so fearful a malady. As it prevails more or less in some situations every season, whatever may be the state of the weather, a cause has been sought in the vicinity of certain plants, the fungous substances attached to which bear a great resemblance to the straw of mildewed wheat. The barberry and several other shrubs have been suspected of extending this evil among the cereal tribes; and various ingenious speculations have been formed to account for the mode of infection. The communications of Sir Joseph Banks to the Board of Agriculture give the fullest view that is anywhere to be found of this obscure inquiry; though it must be acknowledged that his researches were not attended with any practical advantage to the farmer, or with any new lights useful to the Botanist.

Amount of produce.

The amount of the produce raised on an acre of good wheat land varies, in every County, and in every season, from three quarters to ten. We have known a whole field average ten quarters of good marketable grain, a return which may be expressed in another form as equal to eighty Winchester bushels per acre. But perhaps, even in the present improved state of Agriculture, we ought to consider one-third of that quantity as the usual return throughout the Kingdom.

Barley.

Succession.

Varieties.

We proceed now to *Barley*, in regard to which every one knows that it grows best on light loams, and even on a sandy soil, if properly manured. It usually succeeds turnips, potatoes, beans, peas, or tares. But whatever may be the crop which precedes it, the soil must be brought by repeated ploughings to a pulverized state, so as to ensure an equal vegetation. In Suffolk, when Barley follows turnips, it has long been a practice to drill the seed without ploughing; whereas in Norfolk, where this crop is carried to great perfection, the land is carefully prepared by the most assiduous labour. Of this grain there are several species cultivated in Britain, and even different varieties of these species. The two-rowed species, or *Hordeum distichon* of Linnæus, includes sundry varieties, which are known by familiar names among the rustics of both divisions of the island. The early and late, or *hot* seed and *cold* seed, are distinctions universally recognised. To the first of these belongs the Scotch barley, as well as the Rathripe, Hotspur, and Sprat, which are also denominated the Battledore, Fulham, and Putney, from being cultivated in the neighbourhood of those places. The second species is the *Hordeum vulgare*, or *tetrastichon*, which is likewise described as *bear* or *bigg* in the Northern Counties, and is found to answer well on elevated situations and inferior soils. The *Hordeum hexastichon*, or six-rowed Barley, is a species which has a strong reed or straw, grows rapidly, and ripens early, is very hardy, and withstands the severity of Winter; whence it derives its characteristic appellation of *Winter Barley*. It is very generally cultivated in Russia, and as far North indeed as any corn is raised; but as the quality is rather coarse, and fitter for meal than malting, it has not obtained a very favourable reception among our farmers, especially in the more fertile parts of the country.

Sowing.

From the beginning of April to the middle of May is esteemed the best time for sowing Barley; bear or bigg, being an earlier, as well as a hardier kind, may be sown somewhat later. As it suffers much from weeds in a wet season, it ought to be drilled rather than sown broad-cast. The quantity of seed varies according to the condition of the land from two to four bushels. We may remark that of late years it has become customary to throw Barley into the ground at an earlier period than formerly; and hence nothing is more common than to see our farmers occupied with this crop about the middle of March. In some cases, Barley comes up irregularly and ripens unequally. To obviate this inconvenience it has been recommended to steep the seed before committing it to the soil, not only to promote a more rapid vegetation, but to render it more uniform. Some Agriculturists add a little soot to the water, with the view of destroying vermin, which are occasionally found to attach themselves to the husk of the grain.

Care in harvesting.

No crop requires greater attention in harvest, especially in bad weather, than Barley. When it is fully ripe the straw becomes brittle, so that the ears are exceedingly apt to break off, if frequently or roughly handled. The intelligent farmer, therefore, cuts it down, while the straw yet retains a certain portion of its sap and the grain is not fully hardened. Similar care is necessary in threshing, especially in separating the spikes, or *awns*, as they are provincially denominated, from the ear. For this purpose, some threshing-mills are furnished with what is called a *hummelling* machine; and where this is wanting, it is customary to put the grain, accompanied with a portion of threshed straw, a second time through the threshing apparatus. Where Barley has been mown, the whole of the straw requires to be twice threshed, independently of the necessity of getting rid of the spikes, which sometimes adhere tenaciously to the grain, if not completely ripened.

Produce.

The produce of Barley, taking the average of England and the South of Scotland, has been estimated at thirty-two bushels; but when Wales and the North of Scotland are included, where, owing to the imperfect modes of culture still practised, the crops are very indifferent, the general average over the whole will not perhaps exceed twenty-eight bushels per acre. Restricted to the County of Middlesex, the average produce is rated at four quarters of grain and two loads of straw.

Rye.

Rye, although less used in Britain than other culmiferous crops, is nevertheless entitled to a place in the list of our Agricultural productions. It is said to be a native of Crete; but it is doubtful whether it can now be traced to any particular Country. It has been cultivated in Europe from time immemorial, and is considered as coming nearer in its properties to wheat than any

Varieties.

other grain. In most parts of the Continent it is more common than wheat, being a more certain crop, and one which requires less culture and manure. It is the bread corn of Germany and of Russia. The varieties of it are confined to two, the *Winter* and the *Summer*; but there is so little difference between them, that if sown at the same time and in the same field, they can hardly be distinguished from each other. Though it has been considered as the most impoverishing of all crops, it is admitted that it will make a good appearance on a soil much inferior to that required for wheat. It will also prosper in a colder climate, though it is liable to be injured by rains during the Winter as well as in the flowering season; and in these respects it bears some resemblance to the finer grain with which we are now comparing it.

Sowing.

Rye is sown either in Autumn or Spring, and either in broad-cast or in drills; two bushels and a half being the usual allowance to the acre when deposited in the former manner. No pickling or other preparation is given to the seed, there being no reason to apprehend the diseases which that treatment is meant to obviate. The spur. The *spur*, or *ergot*, is by some considered as a fungus, a species of *sclerotium*, somewhat analogous to that which occasions the smut. It is not peculiar to Rye, though it is seldom seen on any other gramineous plant. It is the production of the seeds; is long, horny, and cartilaginous; is sometimes straight, at others curved; and is occasionally found more than two inches in length. The resemblance of this substance to the spurs of a cock has procured for it the name by which it is distinguished. On breaking a spurred seed you find within it a matter of a dull white colour, adhering to the violet skin which surrounds it. Rye thus attacked cannot germinate; and it may be remarked in regard to other grain, the most rainy years are the most productive of this disease; that high grounds were nearly free from it; and that even the lower parts of the same field were more affected than the upper parts. In France, a malady called the chronic, or dry gangrene has been produced by eating ergot or spurred rye. The same effect has been marked in Swisserland, where, it is added, most animals refused to eat the distempered corn. The Royal Society of Medicine at Paris employed M. Tessier, a distinguished Agriculturist and man of Science, to go into the Countries in which the dry gangrene prevailed, and collect a sufficient quantity of cock-spur Rye for the purpose of making experiments. The result confirmed the opinion of those who attributed the human disease to that of the vegetable. Such Rye sometimes appears in this Country, but no instances are recorded of its producing any such effects; but Dr. Wollaston has stated in the *Philosophical Transactions* several cases in which dry gangrene was occasioned in one family by eating damaged wheat; and nearly the same consequences were produced in a household in Wiltshire by the *Colium temulentum* entering largely into the composition of bread. M. Lagusca relates that the ergot is covered with a thin pellicle, and filled with a grey powder. It is collected as a medicine in Spain by women and children, who wade in the fields of standing Rye for the purpose; but as only a very small quantity can be obtained, it is sold at a high price as an article of the *Materia Medica*.

Culture, &c.

The culture, harvesting, and threshing of rye does not differ essentially from the same processes as applied to wheat; and the produse, in similar circumstances, is nearly equal. Sir H. Davy found in one thousand parts of Rye, sixty-one parts of starch and five parts of gluten. Professor Thaer maintains that Rye is the most nourishing grain next to wheat. It contains an aromatic substance, which appears to adhere more particularly to the husk, since the agreeable taste and smell peculiar to Rye-bread, are not found in that which is made from Rye-flour which has passed through a very fine bolting cloth; while the fragrance may be restored by a decoction of Rye-bran in the warm water used to make the dough. This substance is thought to facilitate digestion, and to have an action peculiarly fortifying and refreshing on the animal frame. In this Country accordingly, Rye is chiefly used for gingerbread, and abroad in the distilleries, where it affords a powerful and exhilarating spirit. The best Hollands is made of Rye, well selected and prepared by the manufacturer. The straw, too, is much prized for work, resembling that of Dunstable.

Oats.

Next to wheat and barley there is no grain more common in the Northern parts of Europe than *Oats*. Although its native Country be unknown, the culture of this valuable crop is confined in modern times to districts of which the latitude is higher than the middle Provinces of France. In the Southern Departments, as well as in Italy, Spain, and Portugal, it is almost entirely unknown; being unsuitable to the climate not less than to the wants of the people. Oats require an atmosphere which is at once cool and moist; for in the absence of rain, and affected by a temperature above sixty degrees, the panicles become so contracted that they cease to afford sufficient nourishment to the ears, which thus never become plump, but are thick in the husk, long-awned, and unproductive in meal. This is very often the case with oats in Scotland in a dry year, and in the South of England almost every season.

Varieties.

There are many varieties of this corn, which are known to the farmer under a corresponding number of descriptive appellations. First there is the white or common Oat, then the black, the red, the Polish, the Dutch, the Potato, the Georgian, the Siberian, the Angus, the Blainsley, the dun, and the Winter Oat. The Potato, which is distinguished by having large, white, plump grains, is now almost the only Oat raised on well-cultivated lands, whether in England or Scotland, and usually brings a higher price in the London market than any other variety. It may be remarked, however, that, while the Potato and Polish are the fittest for low situations, where the soil is rich and the air warm, the red kind answers best on elevated grounds and under a less genial climate.

Culture.

Oats grow well on any texture of land, from the stiffest clay to moss or bog, provided it be sufficiently dry. Nor does the soil on which they are cultivated require any great degree of preparation. It is generally the first crop sown on newly broken-up grounds, as the radical fibres do not, as in the case of wheat and barley, depend on that pulverized condition of the mould which results from protracted labour. In regular rotations this usually follows grass; sometimes, upon land not rich enough for wheat, that had been previously fallowed or had carried turnips, after barley, but rarely after wheat, unless from particular circumstances cross cropping becomes a necessary evil. One ploughing is generally given to the grass lands, commonly in the month of January, so that the benefit of frost may be gained, and the surface rendered sufficiently friable for receiving the harrow. In some cases a Spring furrow is given when

Oats succeed barley or wheat, especially when grass-seeds are to accompany the crop. The best Oats both in quantity and quality, are always those which succeed grass; indeed no kind of grain seems better fitted by Nature for foraging upon grass lands, as a full crop is usually obtained in the first instance, and the field left in good order for succeeding ones.

Sowing.

The season for sowing this corn extends from the beginning of March to the end of April. About the middle of the former month is the time fixed on by the best farmers. In some parts of Ireland, the Dutch Oat is sown in Autumn; in consequence of which it is ripe nearly a month earlier than such as is postponed till Spring, an object worthy of attention in so moist a climate.

Produce.

Wire-worms.

As Oats are more carefully cultivated in the Northern Counties than in those Southward of Trent, the produce in the former is correspondingly greater, amounting in some cases to fourteen or fifteen quarters per acre. It is a grain besides which is subject to much fewer diseases than the more delicate species of corn. The smut sometimes, indeed, makes an inroad upon it, but the injury which is oftenest inflicted upon it arises from wire-worms, that is, the *larvæ* of insects which generally abound in lands newly broken up from turf. The best mode of obviating this serious evil is to put off the ploughing of the field till the period at which it is to be sown; for by this means the insect or grub, as it is usually called, is turned down, and before it can work its way to the surface, the corn has grown up beyond its reach. In this way gardeners destroy or retard the progress of the gooseberry caterpillar by digging under the bushes; for it is found that the eggs and *larvæ* of insects, like weeds and bulbs, when buried too deep in the ground, have their period of vegetation delayed, and sometimes the vital principle entirely extinguished.

Value of straw.

Every one knows that the straw of Oats is more valuable as forage than that of any other corn crop, and is even advantageously used as a substitute for hay during the Winter months, both for farm horses and cattle, in some of the best cultivated districts in the Kingdom.

Peas and Beans.

Peas and *Beans* were at one time more generally cultivated than they are at present, being regarded chiefly as the means of cleaning foul ground, and preparing it for wheat or barley. But since the use of green crops has in a great measure superseded the necessity of that expedient, Beans are confined almost exclusively to clays and strong loams, on which turnip cannot be successfully raised. There they succeed wheat or oats, and sometimes also clover or pasture grass.

Culture.

In preparing ground for Peas and Beans, it ought to be deeply ploughed in Autumn or early in Winter; and as a second or even a third furrow must be given in the Spring, it is usual to make one of them a cross-ploughing. The mode of manuring depends upon that of sowing. If the seed is to be scattered in the broad-cast way, the dung should be ploughed down in the fall of the year; but if it is to be deposited in the furrows or in drills, the manure should be laid in with it, so as to afford the most speedy and active cooperation with the soil. The remarks which have been made on drill-husbandry in general apply to the management of this crop, and need not be repeated. Suffice it to add, that Beans when sown alone are commonly planted in rows, at the distance of nine, eighteen, or twenty-seven inches; the last being the usual interval when they are meant to be cultivated by the labour of horses instead of hand-weeding and hoeing.

Sowing, &c.

Produce.

The time of sowing varies from the end of January to the end of March. Both in the broad-cast and drill husbandry, it is common to mix a few Peas with the Beans, because the mixture at once improves the quality of straw when used as fodder, and affords a ready means of binding the sheaves in harvest. The most approved method of reaping this crop is with the sickle, but it is sometimes mown, and in a few instances pulled up by the roots. The amount of produce, as in the case of all pulse grains, is very variable and even precarious; and were it not that it is still esteemed an improving crop, it would not be so generally adopted without the certainty of a higher remuneration in the market.

Tares.

Varieties.

Tares, which in some parts of the Kingdom occupy a considerable share of attention, are found to succeed best on gravelly loams; but they produce a tolerable crop on almost every variety of soil, if properly cultivated and manured. There are two varieties of the Tare, distinguished chiefly by the period of sowing, the *Winter* and the *Spring*; and although it be difficult to discriminate the seeds of these varieties, they should always be kept separate, because each thrives decidedly best in its own season. Winter tares are sown from August till October; earlier on poor soils and exposed situations than on richer and more sheltered lands. The plants should be fully established in the soil before the approach of the cold weather. The Spring kind is sown about the beginning of March, when it is intended to ripen the seeds; but when the crop is to be used as green food, the process may be postponed two months later. Sometimes the insertion of the seed of Spring Tares is delayed till June, when a quart of coleseed is given to each acre, for the purpose of supplying weaned lambs in Autumn with an excellent food. This method is successfully practised on the Down lands in the County of Sussex.

Sowing.

Produce.

Tares are generally sown broad-cast, although, on good soils, drilling is found to remunerate the additional labour by a more abundant return. In Middlesex the produce amounts to about twelve tons per acre, which, when converted into hay, is reduced to three or four tons according to the nature of the season. The most beneficial application of this crop is soiling with horses or other live stock on the farm; but for this purpose it should be allowed to reach a considerable degree of maturity. All descriptions of animals thrive upon it. A single acre of Tares has been known to maintain four horses in better condition than five acres of grass; and twelve horses and eight cows have been kept three months upon eight acres of Tares, without the addition of any other food. It is asserted, too, that the milk of cows fed with this vegetable is so much improved that it yields a greater proportion of butter than can be produced by the best grass-feeding.

Useful species.

Some other species of this plant are recommended to the attention of the Agriculturist; such as the *bush vetch*, which shoots early in the Spring, vegetates late in Autumn, continues green all Winter, is excellent pasture, and on fertile soils might be converted into hay; and secondly, the *tufted vetch*, which rises to a considerable height, and affords abundant foliage, so that it might likewise be used as green fodder, or prepared for hay. Lean cattle, it is said, have been greatly improved by feeding on it. The *everlasting pea*, or *Lathyrus latifolius*, is likewise a plant of large growth and foliage, and has been warmly recommended as a good material for green food or hay, being of a very nutritious and fattening quality. *Buck-wheat* is occasionally cultivated for the same purpose, as well as *chicory*, or *wild succory*, also a succulent, herbaceous plant extremely useful in the dairy and feeding-house.

Potato.

There is no production of the soil which the necessities of life have of late years raised into higher importance than the *Potato;* native of a warm climate, and yet naturalized in all the Countries of Europe. Its history is involved in some obscurity, and the precise period of its introduction has not yet been ascertained. From the History of Plants by Gerard, published in the year 1597, there is no doubt that the Potato was known in England at a somewhat earlier period. He speaks of two kinds, the *common* and the *Virginia*, which he cultivated in his garden; and yet nearly a century and a half elapsed before this valuable root became a general article of food.

Varieties.

The varieties of this plant are now almost as numerous as that of the dog; the distinction being founded chiefly on the colour of the Potato itself, or of the flower which it exhibits when in full growth. In Lancashire, where it is cultivated with much attention, there are known no fewer than twenty varieties of the early description, and fifteen of the late. But this minute subdivision might be carried to a still greater extent. New varieties are obtained every day by raising a crop from seed, by which the quality and productive powers of the plant are said to be greatly improved. When the apples come to maturity and begin to drop from the stem, they are collected and preserved among sand till the Spring, when they are bruised either among the sand, or fresh mould procured for the purpose, by means of which the seeds are separated and mixed with the earth. They are then sown or scattered on a well-prepared or garden soil; and when the rough leaf appears, and the plants have sufficient strength to be safely handled, they are removed to another bed of fresh mould, where they are placed in rows and kept free from weeds during the Summer. In Autumn clusters of small Potatoes are found at the roots; these are planted next Spring, and so on successively three years, at the end of which they attain their full size. It must be noticed, however, that the earlier varieties do not bear flowers, and consequently, do not produce apples; but by removing the earth from the roots, and the small Potatoes themselves as they began to form, Mr. Knight, the President of the Horticultural Society, succeeded in forcing the plant into blossom, and thus obtained seeds from the early as well as the common kinds.

Culture.

The Potato loves a soil which is rather loose and porous; nothing being more fatal to its success than stiff, retentive land. In many parts of Ireland, it is planted on what are called lazy-beds; the sets being placed on the surface, and covered with earth dug out of a trench formed round them. But good farmers prepare their fields for Potatoes nearly in the same manner as is practised in turnip husbandry. The land is usually ploughed in Autumn, an operation which is repeated once or twice in the Spring; and a copious supply of manure is deposited with the seed, either in furrow or drill. Some Agriculturists have discovered an advantage in bestowing a plentiful dunging on the previous crop, rather than on the Potatoes themselves; for in this way the excessive luxuriance of the stems is prevented, while the quality of the root is greatly improved.

Stiring the earth.

No crop is more benefited by the care which is bestowed on weeding and hoeing. The earth ought not only to be kept clean, but also to be frequently stirred, and raised round the roots of the plants at the several stages of their progress. As the Potato is now almost universally cultivated in drills, the greater part of the labour is performed by horses; but whatever may be the species of industry required, the farmer should not withhold it, for nearly in proportion to his exertions in that way, will be the amount of his produce.

Planting.

It has been found by those who have instituted experiments on the comparative advantage of planting entire Potatoes of a larger or smaller size, cuttings of different sizes with one or more eyes, or shoots only, that middle-sized whole Potatoes, or large cuttings of large Potatoes, afford better crops than smaller Potatoes entire, or small cuttings, or the eyes or shoots alone. Considerable diversity, too, in the amount of the produce was occasioned by placing the sets in the rows at various distances, from six to twelve inches. With the view of saving seed in times of scarcity, the shoots only are employed; but this economy is counterbalanced by many disadvantages. The shoots cannot be planted so early; many of them being weak afford little or no produce, and the crop is generally later in reaching maturity. In the use of the eye, or root-bud of the Potato, the success has been various. In some cases the produce seems to be equal to what was obtained from larger sets; but in others, feeble stems and a diminished return have afforded ample evidence that this mode of propagation ought not to be relied upon by the British farmer.

Diseases.
The Curl.

The prevailing disease of the Potato is the *curl*, which originating in Lancashire in the year 1778, soon spread very rapidly, especially in those districts where the culture of this valuable root was the most extensive. The alarm excited by this occurrence led to numerous investigations with the view of discovering the cause. At present the opinion on this head, which seems deserving of the greatest attention, is that entertained by some members of the Caledonian Horticultural Society, who ascribe the malady to an undue ripeness of the seed. To procure, therefore, a sound, healthy stock, it is recommended to select seed from a high part of the country, where owing to climate, and other circumstances, the tubers are never over-ripened. With the same view, such Potatoes as are intended to supply seed for the following season, should be planted at least a fortnight later than those which are meant for the table, and taken up as soon as the stems begin to display a yellow-green colour.

Cutting the blossoms.

Among the various methods which have been devised for increasing the produce, it has been a practice with some Agriculturists to cut away those parts of the plant which contain the flower before the blossom appears. It has been ascertained by Mr. Knight that this vegetable possesses two modes of securing its reproduction; the one by producing tuberous roots, and the other by the general mode of flowers and seed-vessels; and that in both these operations. Hence it has been inferred that if we can prevent the consumption of it in either of them, we shall make it act more strongly in the other. On this principle, if a Potato plant is carefully deprived of its tubers as soon as they are formed, it will be made infinitely more productive of blossoms and seeds. On the other hand, if its blossoms are picked off, and it is prevented from forming any seed at all, the fluid which would have been employed in that opera tion, will be expended in forming an increased crop of tubers.

Produce.

In regard to the average produce, we cannot form an accurate judgment without taking into account such a variety of circumstances of culture, fertility, and climate, as would render the result inapplicable to any great extent of country, even in the same neighbourhood. It has been stated by some writers to vary from five to ten tons, according to the nature of the soil, and the skill of the husbandman. In Yorkshire, from 300 to 400 bushels of the finer variety, and from 400 to 500 of the coarser sort, are considered a good crop. We have heard that, in some districts of Kent, more than 600 bushels have been raised from an acre, and that even a much larger amount has been obtained, in a very favourable season, and from a soil peculiarly rich.

Turnip.

Varieties.

Next to potato in importance we may place Turnip, viewed at least as the means of improving land, of supplying to the Agriculturist a valuable species of food for his cattle. The introduction of this plant, together with clover and the artificial grasses, formed a new era in the progress of our native husbandry. It is true that Turnip does not succeed on every kind of soil, particularly such as are stiff and clayey; but on dry loams, and indeed on all of a loose texture, managed according to the best courses of cropping, it enters into rotation every fourth or sixth year. The species usually cultivated in the improved districts are the *white globe*, which ripens early, and gives a full crop; the *yellow*, which has the advantage of being more hardy, and is usually meant to follow the other in Spring; and thirdly, the Swedish or *ruta baga*, which may be preserved for consumption till the end of May.

Culture.

To secure a good return the farmer must have his land well pulverized, and cleaned. The manure ought also to be carefully prepared, and in a state of minute division, otherwise the work will be clumsily performed, and much of the seed lost. We need not add that the process of sowing is usually conducted by means of the drill-machine. The time of sowing the several varieties is somewhat different; the Swedish being put in first, and the yellow, and both about the end of May. But as these kinds are much less extensively cultivated than the white, the principal seed-time takes place in the month of June. The quantity of seed allowed to the acre does not exceed two pounds, which, though more than sufficient to stock the ground with plants, is thought necessary for securing a good crop on most soils. As soon as the rough leaf, as it is called, is developed in the young shoot, the hoes must be employed to thin the rows, and destroy the most obtrusive weeds. Next follows the horse-hoe to stir the soil and clean the surface; an operation which it is sometimes necessary to repeat, should the field not have been brought into good order by previous ploughing and eradication.

Injurious insects.

So far as labour is concerned there is no ground, generally speaking, to dread the failure of a crop in an ordinary season. But the husbandman has obstacles to encounter which no exertion can remove, and, we may add, which no care can altogether obviate. His greatest enemy is the Turnip fly, the *Chrysomela saltatoria* of Linnæus, which by preying upon the leaves of the young plants very soon destroys them. The canker, so much dreaded in Norfolk, is to be referred to the ravages of another insect, the *Tenthredo oleracea* of the same Naturalist, which is wafted over in myriads with the North-East wind from the Continent, and in the course of a day or two covers whole fields. The black caterpillar commences its depredations on the Turnip plants after they have made some progress; and it is sometimes assisted in its work of destruction by the grey slug, not less formidable in certain situations than any of the others.

Remedies.

Various means have been devised to prevent the ruin occasioned by these insects, but hitherto without success. It has been recommended to steep the seed in water, train-oil, linseed oil, or some similar fluid, twenty-four hours, and after mixing it with finely sifted earth, to deposit it immediately in the drill. The strewing of quick-lime, vegetable ashes, soot, or barley chaff, and the sprinkling of lime-water, tobacco-water, and some other liquids, have been practised for the destruction of the fly and slug. Rolling the ground with a heavy roller in the night, when the insect proceeds from its lurking place, has been adopted by some farmers, but with doubtful success. It has been suggested that as the radish leaf is preferred by the slug to that of the turnip, a little of the former should be sown along with the latter; and as the radish appears first, the chance of an escape is thereby secured for the main crop.

Other diseases.

But Turnips are, besides, exposed to a disease in the root. A large excrescence forms below the bulb, which after a certain period becomes putrid, and emits a very offensive smell; an affection which has been ascribed to a puncture made by a grub or other insect in the vessels of the tap-root. It occurs most frequently in dry seasons; and the only antidote that has been devised is to enrich the land by means of assiduous culture and good manure. There is another distemper familiarly known in the country by the name of *fingers and toes*, when the plant, instead of forming bulbs, sends off a number of separate roots. In some cases the bulb itself is divided into lobes, but very often the tap-root is the part affected while the bulb remains untouched. These unhealthy indications are frequently observed at an early period, and sometimes before the appearance of the rough leaf. All inquiries into the history or origin of this disease have failed to discover its true source; at least it cannot be traced to any peculiarity in the seed, the period of sowing, or even in the soil. Some writers have conjectured that it may be occasioned by a wound inflicted on the roots by an insect too small to be observed, or which retires after it has done the mischief. Marl, or fresh mould mixed with lime, has been applied to the land as the only remedy which seemed likely to prove effectual.

Produce.

The produce of a Turnip crop varies to a great degree in different Counties, according to the nature of the soil, the management, and the weather. Fifteen tons are reckoned a moderate return, and perhaps the weight does not average much higher throughout the Kingdom; but we have known instances where it amounted to fifty, and have heard of others still more abundant.

Carrot.

The *Carrot*, though long grown in our gardens, is comparatively but of recent introduction into Agriculture. It seems to have been cultivated from an early period in Germany and Flanders, and brought over from the latter Country to Kent and Suffolk, in the XVIth Century. As it requires a deep soil inclining to sand, it can never be so generally raised as the potato and turnip, which come to maturity on a greater variety of grounds. On other accounts it is less prized, as a regular crop, by Agriculturists than it was a few years ago; and even in Norfolk, where it was very successfully cultivated, we are informed that it is sown in much smaller quantities than it was about the beginning of the Century. It is said that the consumption of Carrot seed in that County alone has diminished from three or four tons a year to as many hundred weights.

Varieties. The varieties of the Carrot which appear in our gardens are numerous, and may be increased to a great extent by the usual means; but the only sort adapted for the field is that which is called the long red. The farmer should be aware that new seed is most essential, as it will not vegetate the second year.

Culture. We have already stated that the best soil for the Carrot is a deep rich sandy loam; and in preparing it for crop it ought to be ploughed before Winter, in order that it may be pulverized by the frost, and in the Spring well stirred to the depth at least of a foot. This deep tillage may be perfectly accomplished either by means of the trench-plough following the common one, or by the common one alone with a good strength of team; but the former method is to be preferred wherever the lands are inclined to be stiff or heavy. In Suffolk, the farmers sow Carrots after turnips, barley, and peas, set upon a rye grass lay; the crops upon the first have generally been most productive; next to that they prefer the last. In the former case, they feed off the turnips by the beginning of February, and then lay the land up in small balks or furrows, in which state it remains till the second week in March, when it is harrowed down, double-furrowed to the depth of about twelve inches, and the seed sown.

In regard to climate, the Carrot and turnip require nearly the same temperature; but the former, from the depth to which the roots penetrate the soil, thrive better than the other in dry warm weather. The season for sowing is the last week in March, or the succeeding one in April; though the first is generally preferred, it being found that the early crop is usually the most productive.

Manuring. According to some authors, manure should not be given to Carrots the year they are sown, as it is alleged that when the roots come in contact with it they become forked, scabbed, and wormy. This, however, will only take place in cases where recent unfermented dung has been applied; or where other manure has not been properly divided and broken into small pieces. The best farmers in England always use manure; for, though it has been found that good crops may be occasionally raised in a rich soil without it, the general rule is, that a liberal allowance of the best dung is quite essential to an abundant return in ordinary circumstances.

The usual preparation of the seed for sowing is to mix it with earth or sand to make it separate more freely; but some add water, turning over the mixture several times, and thus bringing the seed to the point of vegetation before it is sown. In France, night-soil is sometimes used instead of earth, and the drainings of a dunghill instead of water. The quantity of seed when Carrots are sown in drills is estimated at two pounds, while for broad-cast three times as much is found necessary.

Produce. The produce of an acre, according to Mr. Young, averages three hundred and fifty bushels; but Mr. Burrows states, in his communications to the Board of Agriculture, that his land yielded eight hundred bushels per acre, a produce which considerably exceeds the largest crop of potatoes.

Uses. The Carrot is extremely valuable as an article of rural economy. It is used for feeding all kinds of stock, serves well in the dairy, and is equal to oats for the sustenance of labouring cattle. The quantity of nutritive matter in this plant, as ascertained by Sir Humphry Davy, amounts to ninety-eight parts in one thousand, of which three are starch, and ninety-five sugar. Owing to this circumstance, they yield more spirit to the distiller than the potato, averaging, it is said, twelve gallons per ton.

Mangold-wurzel. The *Mangold-wurzel*, or *field-beet*, has of late years been pretty generally cultivated in some of the most improved districts of the Kingdom. It is supposed to be a mongrel between the red and white beet, though it has a much larger bulb than either, which in some varieties grows in great part above the ground. It has been a good deal cultivated in Germany and Swisserland both for its leaves and roots; the former are used either for spinach or given to cattle; and the roots are set apart, as well for the latter purpose as for the distillery and sugar-house. It has been doubted whether it possesses any advantages over turnip for the general purposes of Agriculture; and perhaps the main ground of preference consists in its adaptation to more tenacious soils than answer for turnip, and in its being less exposed to depredation in the neighbourhood of large towns. It has been ascertained that any kind of land will suit this plant, provided it be rich; and immense crops of it have been raised even on strong clays. The variety which is most esteemed in Germany is slightly tinged with red, although for distillation and the manufacture of sugar, a selection is made of that particular kind which is distinguished by a pale yellow colour.

Culture. The ground should be prepared for it exactly in the same manner as for turnip, and the process of sowing should be conducted on the system of drill husbandry. Some farmers, however, prefer to dibble in the seed, as they are thereby saved the expense of thinning. In either case, the work should be done about the middle of April. The produce of this crop, in similar circumstances, does not fall short of Swedish turnip; but the nutritive matter afforded by mangold-wurzel is considerably greater. In 1000 parts, that matter amounts to 136, of which 13 are mucilage, 119 sugar, and 4 gluten. Hence it is manifest that an acre of it will afford more nourishment than turnip, carrot, or parsnips. As food for cows, it has generally been preferred, as it gives no bad taste to the milk or butter. Near London, it is very much used for this purpose; the tops are first taken off and given by themselves; and then the roots are taken up, washed, and given raw. In Britain, the abundance of corn and sugar has precluded the use of this vegetable from entering into our manufactures; but in France the processes introduced during the domination of Bonaparte have not yet been everywhere relinquished.

Parsnip. The *Parsnip* has not yet been so generally received into British Agriculture as to merit much attention in an outline of our crops. In Jersey, where it is extensively cultivated, beans are commonly grown along with it; the former being first dibbled in, and the latter afterwards sown broad-cast. For fattening cattle, it is considered equal, if not superior to carrot, as it gives an exquisite flavour and juicy quality to the meat. It has the same good effect on milk and butter when cows are fed on it. When sown in drills, the quantity required is about two pounds the acre, and the proper season is the month of February. But notwithstanding the inducements now mentioned to the culture of this crop, it will not, it is probable, ever take its place in a regular rotation; because while, like carrot, it requires much manual labour, the variable nature of our climate must ever render the return very uncertain.

Cabbage.

The *Cabbage*, though a nutritious plant, and quite suitable for field cultivation, has not been found profitable as an article of Agricultural industry. One reason why so much has been said in its favour, by Mr. Young and other writers, whose experience has been confined to the Southern Counties of England, may be discovered in the circumstance that they compare its produce with the quantity of turnip raised on an equal space of land. But it is well known that from the nature of the soil, the climate, and the mode of husbandry, the weight of turnip raised in those districts falls greatly short of the average amount as applied to the Kingdom at large; whence it follows that their estimates must be carefully examined by cultivators whose farms are differently circumstanced, or whose management is directed by more scientific principles in respect to the growth of turnip.

Culture.

Produce.

The Cabbage requires a rich soil inclining to loam. The mode of cultivation greatly resembles that which proves most successful with potato, the plants being inserted along the summit of each ridgelet when there is a suitable depth of earth. The usual season is March, but they may be planted as late as June with every prospect of a fair crop in November; and on this account they are occasionally substituted for turnip, which has given way, either from want of rain or a defect in the seed. The produce is said to be from thirty-five to forty tons the acre; and Sir H. Davy found that 1000 parts of cabbage gave 73 of nutritive matter, of which 41 were mucilage, 24 sugar, and 8 gluten.

Rape.

Rape has of late years claimed for itself a place in the catalogue of field productions; being found valuable not only for the oil which is expressed from it, but also for feeding sheep on land not well adapted to turnip. It is cultivated on a variety of soils, as a first crop after paring and burning, and when old grass-lands are brought into tillage. Upon fields kept under the plough it comes into the rotation as a green crop; and the preparation and after culture are the same as for turnip. A variety of this plant is extensively cultivated in Flanders chiefly for the sake of the oil expressed from its seed. The husks in the form of cake or dust, after the oil is withdrawn, constitute an important manure, to which we have already invited the attention of the reader. The following remarks by the late Mr. Culley of Northumberland, comprehend all that are necessary to be said on this subject.

Mr. Culley's Remarks.

"Rape may be sown from the 24th of May to the 8th of June, but comes to the greatest growth if sown in May. If sown earlier, it is apt to run to seed. From two to three pounds of seed is required per acre sown by a common turnip-seed drill. But as Rape-seed is so much larger than turnip-seed, the drill should be wider. When hoed, the Rape should be set out at the same distance as turnip plants. The drills should be from 26 to 28 or 30 inches, according to the quantity of dung given. As many ploughings, harrowings, and rollings should be given as may be necessary to make the soil as fine as possible; the produce will be from twenty-five to fifty tons or upwards. But it is not so much the value of the green crop, as the great certainty of a valuable crop of wheat that merits attention. The sheep are put on from the beginning to the middle of August; they must have the Rape consumed by the middle, or at latest by the end of September, so that the wheat may be sown before the Autumnal rains take place. The Burwell red wheat is always preferred. The land must be made as clean as any naked fallow. There is scarcely an instance known of a crop of wheat sown after Rape and eaten off with sheep being mildewed; and the grain is generelly well perfected."

Clover.

Varieties.

Culture.

In the modern scheme of cultivation by rotation of crops, *Clover* enters into the regular succession. Before it was introduced, it was thought necessary whenever land was exhausted by grain crops, to leave it in a state of nature and inactivity for several years; after which it was again put under the plough. At present, however, such a miserable expedient is superseded by the practice of raising green crops and corn crops in a certain order on rich soils; while in regard to poorer lands, which do not permit so close a succession, Clover is useful as the means of converting them into excellent pasture. Red clover, or, as it is sometimes called, broad clover, is the species most commonly grown on fields which bear an alternation of white and green crops, because it yields a larger produce for one year than any of the other sorts. The white or yellow varieties are seldom mixed with it, unless it be the intention of the farmer to lay down his ground in pasturage. On rich, clean soils ten or twelve pounds are sufficient for the acre, but on less fertile soils, especially of a stiff quality, sixteen or eighteen pounds are required. When it is to be cut for hay, thin sowing is recommended. It may be put in during any of the Spring months, with the new corn, or among young wheat. When it is cultivated with a drill crop, it is sown broad-cast, as soon as the grain is drilled, and covered in with a slight harrowing. Sometimes it is sown before the roller, when the barley is a few inches high; and sometimes it is introduced during the operation of hoeing, whether with the hand or by means of the horse apparatus. When the field is intended for early pasturage, it is usual in some districts to sow ray, rib, and similar grasses with the Clover; and in this way a more luxuriant herbage is produced, especially on the later kinds of soil; but when the crop is to be cut green, it is better to sow the Clover unmixed.

Cut while growing.

It is admitted that the greatest advantage is derived from this crop by cutting it in the green state, for feeding horses and cattle. Applied in this way, it is asserted that the Clover supports more than twice the quantity of stock, than by pasturing or feeding off in the field; and the additional manure thereby obtained is an ample compensation for the expense of cutting and carriage. Mr. Kent states the difference in the following terms. "The quick growth of this grass after mowing, shades the ground, and prevents the sun from exhaling the moisture of the land so much as it would if fed bare; consequently, it continues to spring with more vigour, and the moment one crop is off another begins to shoot up. Whereas when cattle feed it, they frequently destroy almost as much as they eat; and besides bruise the necks of the roots with their feet, which prevents the Clover from springing so freely as after a clean cut by the scythe. In hot weather, which is the common season for feeding Clover, the flies too are generally so troublesome to the cattle, that they are continually running from hedge to hedge to brush them off; by which it is inconceivable what injury they do to the crop. But when they are fed in stables and yards, they are more in the shade, they thrive better, and at the same time consume the whole of what is given to them without waste.

Seed clover.

When clover is intended to produce seed, it is sometimes cut for a first crop of hay, and the seed is obtained from the second crop; but it is a better practice to eat it well down in the early part of the Spring by ewes and lambs, for in this way the land is less exhausted, besides having afforded the peculiar advantage of early green food for the live stock. The crop remains till the husks or blossoms become quite brown, and the seeds have acquired firmness. After being cut down it is left on the field till it is dry and crisp, that the seeds may be fully hardened. It is then put up, and the seed is threshed out in the course of the Winter; a process which might be successfully managed by the application of a mill or other machinery.

Rye-grass with clover.

It is usual to sow rye-grass with clover, whether the land be meant for hay or pasture; the former commonly at the rate of a bushel the acre, or a smaller quantity if the soil be fertile and in good order. It may be of either the annual or perennial variety, if it be understood that the herbage is to be continued for only one year; and the former produces in general the more bulky crop.

Choice of seeds.

In the selection of both these seeds, particular attention should be paid to their quality and cleanness. The purple colour of the clover denotes that it has been ripe and well saved, and the seeds of weeds, if there be any, will be the more readily detected. Red clover from Holland and France has been found to die out in the season immediately after it has been cut or pastured; while the English seed produces plants which stand over the second, and even the third year. Between the seeds of the annual and perennial rye-grass the difference is hardly discernible; and therefore unless it be of his own growth, the farmer can have no certainty that he does not labour under deception in this important matter.

Trefoil

Trefoil is not only a useful plant in pasture lands, but may also be beneficially employed as one of the cultivated grasses. The stem is more slender, and the growth less luxuriant than common clover. It is sown with oats, or among the wheat crop in the Spring, when it is to be succeeded by grain in the following season; by which means a good feed is obtained for cattle from harvest till the dead of Winter. Trefoil affords good pasturage for all kinds of stock, but more especially for sheep. It is earlier than clover, and comes well in after the turnip and rye crops are consumed.

Sainfoin.

Sainfoin also is a very useful plant, especially on the lighter descriptions of calcareous soils; affording a valuable food in hilly situations, whether as hay or pasturage. It is sown with many of the Spring corn crops, but it thrives best with barley after turnip; and it is recommended by some that only half the quantity of barley used for a full crop should be used in such circumstances. Much of the success in all cases, however, depends on the after management. While some writers advise that it should be cut for hay instead of being pastured; others maintain that it should be neither cut nor pastured till the Autumn of the first year. The diversity of practice here recommended may arise from a difference of the soil, and a greater or less degree of luxuriance in the crop. But in every instance, a crop of hay is taken the succeeding Summer; and the after-grass is fed down, to a certain degree, by any kind of stock except sheep till the month of December.

Its culture.

It is not till the third year that Sainfoin attains its perfect growth; and it begins to decline about the eighth or tenth, unless manure be liberally applied. Coal-ashes, peat-ashes, soot, and malt-dust are employed for this purpose; and when the plants are well established in the soil, top-dressings of this kind, every third or fourth year, retain them in vigour nearly double the period. This crop is useful in its green state for all kinds of stock, although it has been supposed that the flavour of milk is injured by it; but it is more commonly used as hay, as it affords a very nutritious food to working horses as well as other descriptions of cattle.

Lucerne.

Lucerne has for a good many years occupied a part of our best cultivated lands. It grows most luxuriantly on deep, rich, loamy soils, which must, however, be kept dry and well manured. With this view the fields are prepared either by means of fallowing, or by a hoed crop of turnips, carrots, or cabbages. The plants strike deep into the ground, sending up numerous clover-like shoots, which bear blue or violet-coloured leaves. It is extensively grown in the South of Europe, and has been found to answer well in many parts of England, though the principal seat of its culture is Kent. The Roman authors extol this grass very highly and give minute directions for its management; reminding the practical farmer that it requires a deep, friable soil inclining to sand with a subsoil of a similar character; that it must be sown early in the season; kept free from weeds; and occasionally supplied with a top-dressing of manure.

Sowing Lucerne

The seed of Lucerne is of a larger size and paler colour than that of clover. The quantity required in the broad-cast method is from eighteen to twenty pounds per acre; but when drilled in rows twelve inches distant, ten or twelve pounds are said to be sufficient, though our own experience, even on good land, confirms us in the belief that this estimate is rather too low. When the plants are to be raised in a seed-bed, the sowing should be as early as the frosts admit, that they may be fit for transplanting in August. This mode can only be practised on a limited scale, and in order that where the soil is rich the crop may stand thin and regular, and thereby acquire a vigorous growth. Where the labour of weeding and hoeing cannot be perfectly executed, the broad-cast method of sowing may be adopted; but where suitable attention to the land can be bestowed, drilling at narrow distances should unquestionably be preferred.

with other crops.

In a fertile country, there is an obvious advantage in sowing the Lucerne alone, inasmuch as less time is lost, while there is a greater certainty of obtaining a crop. But the sowing with corn on light and porous soils affords the young plants some protection, and also, it is thought, prevents the ravages of the fly. When Lucerne is sown with grain, the quanty of seed used for the latter ought to be smaller than for a separate crop; and we add that for this purpose oats are considered better than barley as they are not so apt to lodge in a moist season.

Culture.

The culture of Lucerne is attended with considerable expense, but, when it succeeds, it brings to the farmer a full remuneration. Being one of the earliest grasses, it is sometimes ready for the scythe about the end of May, and, in favourable soils, it may be cut every five or six weeks throughout the season. Again, besides affording a very nutritious food, it is extremely useful for soiling horses and other cattle, and indeed for all the purposes contemplated by the Agriculturist in raising the artificial grasses. The failure of clover in lands whereon it has been too frequently grown, a fact fully established by experience, may therefore induce practical men to make a trial of Lucerne in places in which it is hitherto little known; and in time it may possibly become so inured to our climate as to grow luxuriantly in parts of the Island, of which the soil and climate do not rank in the first class. It is sometimes used for hay; but unquestionably the most profitable application of it is in its green state, for the soiling and feeding of live stock.

Flax and Hemp.

As Flax and Hemp are very sparingly grown in this Country, we shall hold it sufficient to mention that they both require good soils, and are, at the same time, considered so exhausting to the land as to require a larger price than can be obtained in face of a competition with Holland and Russia. Dutch seed is in higher estimation than any other; it being found that it raises a larger produce than the American, and secures a finer quality than that imported from Riga. In former times the process of steeping and bleaching was both tedious and precarious, for if the weather became wet there was a great risk of losing the whole crop before it could be dried; but this labour and hazard are now precluded by the use of Hill and Bundy's Patent machines, by which the whole preparation of Flax for the mill may be accomplished in the space of six days.

Hops.

The Hop, though largely cultivated in some parts of the Kingdom, is by no means a general product of Agricultural labour throughout the Empire, because it requires advantages of soil and climate which are denied to the greater portion of it. In the most favourable situations it is a very precarious crop, sometimes yielding an ample profit, and at other times not defraying the expense of rearing it. The plant itself, as Mr. Parkinson remarks, is extremely liable to disasters, from its first putting up in the Spring until the time of picking in September. Snails and slugs, ants and fleas, are formidable enemies in the first instance. Frosts are inimical to its growth; and the bines are frequently blighted even after they have reached the top of the poles. Certain green flies which make their appearance in the months of May and June, when the wind is about North-East, often greatly injure them; and they are subject to be damaged by high winds from the South-West. The best situation therefore for a hop-garden is a Southern aspect, well shaded on three sides, either by hills or planting, which is supposed to be the chief protection that can be given them.

Culture.

When it is intended to have a new plantation, the best method is to have the cuttings from approved stock planted out the year before they are wanted in the hop-ground, as the use of plants instead of cuttings not only gains twelvemonths, but they are more certain to flourish, as many of the latter will not take root in a dry season. A small piece of moist land is sufficient to raise plants for many acres and at little expense. In preparing the ground, it is worked with a spade, and set out in ridges about ten feet wide, and two yards between each; having a strip of grass, called a pillar, next every ridge, and an open drain between every two pillars, the depth of which varies according to the soil. Three rows of plants are made upon each ridge, which should intersect each other at right angles. They are generally about six feet distant in the rows, so that the number of plants on a statute acre may be estimated at thirteen hundred.

Expense.

The expense of taking up hop ground is from £5 to £6 per acre, as the price of planting varies with the mode pursued; and if the drains are required to be deep or the soil is particularly strong, a still greater sum will be expended; to which may be added £25 per acre for poles, the rent and taxes, and also the working for three years before many hops can be expected. "The following are termed the annual orders: digging the ground completely over, hoeing the earth from the plants, and cutting off the stock a little above the roots, which processes are called *pickling* and *cutting; poling*, which is carrying the poles from the stacks, and setting them down to the plants with a round implement shod with iron and called a *poy*, having a crutch at the top and a peg through the middle to tread upon; tying the bines round the poles with rushes and pulling up the superfluous bines; hoeing the ground all over with a hoe of large dimensions; wheeling and laying manure upon every plant or hill; covering the manure with the soil, which is done by scraping the ground over with a hoe and is called *hilling;* and *stacking*, which is carrying and setting up the poles into heaps or stacks, after the crop has been taken. The annual expense of these orders varies from £2. 15*s.* to £3. 5*s.* per acre.

Manure.

As to the manure most proper for the hop culture, good stable dung is much used, and is preferred to the manure made by cattle, as the latter encourages ants on strong ground. Woollen rags are the best for forcing a luxurious bine, and if used with judgment are excellent for clay-land; but they are apt to make the hops small if too many are employed. Malt, culm, and dove-manure are excellent; and one complete dressing with lime is very serviceable for strong ground.

Picking, &c.

When the crop is ripe, a proper number of pickers are procured, for whom are provided light wooden frames, called *binges;* they are clothed with hop-bagging, into which the hops are picked off the poles by women and children, having them brought by men, who take them up by cutting the bines about a foot above the ground, and drawing up the poles by an instrument called a *dragon*. Each *binge* has from four to six pickers, and a man attends to one or two *binges* according to the crop; he strips the bines from the poles as they are picked and lays them in heaps ready for stacking; he also carries the hops to the kilns, if near, or to a cart, as they are measured from the *binge*. It is necessary to have a supply of coke in the kilns to dry the hops which are spread on hair-cloth, stretched upon an open floor of wood over the fire, every noon and midnight, so long as the picking continues. They are stirred repeatedly, and when cured are turned off into the store-room to be put into bags and pockets, (after they have been there about a week,) which is done by fixing each bag in a frame and treading the hops in. The excise officer, who attends during the season, then weighs them, and charges twopence per pound for the duty, when they become marketable.

Profits.

From the foregoing particulars, continues Mr. Parkinson, it will appear that there are scarcely any hop-grounds which do not cost yearly upwards of £12 per acre, (exclusive of the picking and duty, which may exceed £20 per acre;) and there are other grounds on which upwards of £20 the acre are expended; so the average may be said to be about £15 per acre, without the picking, drying, and duty. If a good plantation produces ten hundred weight per acre in a crop year, which are sold at £5 per hundred weight, the annual expenses being £20, and the labour and duty £20, the profit will be £10; and admitting that the same ground pays all expenses in a blight year, and supposing this to be every third year, the profits would be nearly £7 per acre annually. But, as the foregoing crop cannot be expected on any ground every other year, the produce of the third year may be stated at five hundred weight per acre, at eight guineas per hundred weight; from which amount must be deducted the annual expenses £20, and the picking and duty £12, leaving as before a profit of about £10.

On a suitable soil, properly managed, a hop plantation may continue in a state of tolerable productiveness, fifteen years or more, but in ordinary circumstances it begins to deteriorate about the tenth year. The expense of forming one has been estimated, including all the expenses of cultivation and building, at from £70 to £100 per acre. The annual dressing, too, absorbs a great quantity of manure, which, of course, must be withheld from the lands under tillage, and thereby give occasion to a certain degree of loss. It may consequently be inferred that the growing of hops, in favourable circumstances of soil and climate, is a profitable application of Agricultural capital and skill.

Other crops.

Our limits will not permit any minute description of a variety of other productions which, in particular districts, occupy the attention of the farmer: such as *fiorin grass*, strongly recommended by the late Dr. Richardson; *woad* and *weld*, articles used for dyeing black and yellow respectively; the *spurry*, or *Spergula arvensis*, a plant occasionally sown on stubble fields; *buck-wheat*, a grain principally used for feeding poultry; *maize* or Indian corn, lately attempted on a small scale; and *kelp*, a marine product raised for the purpose of supplying an alkali or potash, which is found useful both as a manure and in the manufacture of soap and glass. We therefore pass on to another branch of our subject, namely,

The Succession or Rotation of Crops.

Causes of fertility.

It is now one of the best established principles in farming, that land from which the same species of crop is taken for a number of years, is more exhausted than if the same quantity of produce were raised from it, provided the grain or plants were of different sorts. Hence it is an important inquiry, how the kinds of crop best adapted to different situations should be selected, so as to obtain at the cheapest rate, and with the most certain success, those which are the most advantageous and which best correspond with the nature of the land and the husbandman's means of raising them; keeping in view general economy and profit, and the full supply of manure requisite to support the fertility of the soil. In every system of management, a remark made by Dr. Coventry, the late Professor of Agriculture at Edinburgh, should be remembered; namely, that the fertility of any soil is augmented in proportion as it is already fertile; or, in other words, that it is more difficult to raise the fertility of land from the pitch of bearing two quarters to that of three, than from three to five or even six. It is true, as the same author observes, that the circumstances of situation can alone determine what are the most proper species of crops for culture; the proportion in which they should be raised, and the best order or succession with respect to one another. Certain particulars in different cases require the attentive consideration of the husbandman, when about to settle the mode of culture for his arable fields; some of them are of general import while others are more connected with local peculiarities of earth and atmosphere.

Alternate and convertible crops.

In all cases, the main points to be considered are the proper adaptation of the corn crops to the nature and state of the lands, and the judicious intermixture of green crops so as to prevent the exhaustion or deterioration of the soil; that is, the strict observance of the alternate husbandry. In this way the culture of the field approaches to that of the garden, and the impoverishing effects produced by a succession of grain crops are avoided, while the amount of produce is greatly increased. But it ought to be observed that the fertility even of the richest land cannot be retained by a constant course of alternate cropping; while such management on a sandy soil, and indeed on all of a higher description, is positively injurious. For the purpose of keeping up the requisite degree of vigour in such lands, that portion which has produced a herbage crop is allowed to remain in pasture, during one or two years. According to this system, which, to distinguish it from the alternate, is denominated *convertible* husbandry, the same land is at one period under the plough, and at another in pasture grass. In conducting both schemes, the convertible and the alternate, the farmer must not repeat a crop on the same field at too short an interval; and this remark applies to turnip and potato as well as to wheat or rye. A too rapid recurrence is certain to be followed by a diminution in the extent as well as in the quality of the produce.

Proportion of green and white crops.

It has been recommended by the author of the *Survey of Middlesex*, that where the land is of the best quality an alternation of green and white crops may be pursued; that where the land is of a full medium quality, three green crops and two corn crops should be taken; that for ordinary land the proportion should not exceed one corn crop for two green crops; and that for poor exhausted land, as that of the Down and Sheep-Walk description, one grain crop is sufficient for three of potato, clover, or turnip. By cropping in this manner and in the proportions now stated, it is supposed that lands may be kept in a clean state and in a proper degree of fertility; or as the author expresses it, under such management they might be continued in perpetual aration with a constant succession of large products.

Rotations.

According to the proportions just stated, the following series of crops are suggested:

I. Corn, clover, peas; or peas, beans, corn; being two green crops for one of the white kind.
II. Corn, clover, tares, turnips; or corn, clover, peas, and beans; being three green crops to one white.
III. Tares, potatoes or cole, turnips, corn, clover; being four green crops to one of corn.
IV. Peas, beans, corn, clover, tares, turnips; being five green crops to one of grain.

On lands where the convertible husbandry is pursued, horse-hoeing practised, and the green crops sown on ridges at a proper distance from one another, the following Rotations are suggested by Mr. Close for different sorts.

I. On clay soils.
1. Turnips or cabbages.
2. Oats.
3. Beans and clover.
4. Wheat.
5. Turnips or cabbages.
6. Oats.
7. Beans and vetches.
8. Wheat.

II. On clayey loams.
1. Turnips or cabbages.
2. Oats.
3. Clover.
4. Wheat.
5. Turnips or cabbages.
6. Barley.
7. Beans.
8. Wheat.

III. On rich or sandy loams.
1. Turnips and potatoes.
2. Barley.
3. Clover.
4. Wheat.
5. Beans.
6. Barley.
7. Peas.
8. Wheat.

IV. On peaty soils.
1. Turnips.
2. Barley.
3. Clover.
4. Wheat.
5. Potatoes.
6. Barley.
7. Peas.
8. Wheat.

V. On a chalky subsoil.
1. Turnips.
2. Barley.
3. Clover.
4. Wheat.
5. Potatoes.
6. Barley.
7. Peas.
8. Wheat.

VI. On gravelly soils.
1. Turnip.
2. Barley.
3. Clover.
4. Wheat.
5. Potatoes.
6. Barley.
7. Peas.

VII. On light lands.
1. Turnips.
2. Barley.
3. Clover and rye-grass.
4. Ditto, ditto.
5. Ditto, ditto.
6. Peas.
7. Rye.
8. Wheat.

Cross-cropping.

Expense.

These examples are sufficient to illustrate the subject of improved Rotations as explained by Mr. Brown in his *Treatise on Rural Affairs*, but as the best general scheme may be occasionally deviated from with advantage, the same author adds that cross-cropping in some cases may perhaps be justifiable in practice. For instance, we have seen wheat taken after oats with great success when these last had followed clover on a rich soil, though, as a permanent rule, it cannot be recommended. We have heard of another Rotation which seems to come under the same predicament, were it not that, without the test of experience, we must not presume to pronounce upon its merits. The method alluded to begins with a naked fallow, and is carried on with wheat, grass for one year or more, oats, and wheat again, with which the series terminates. The supporters of this plan of cultivation maintain that beans are an uncertain crop and raised at great expense; and that in no other way will corn, in equal quantity and of equal value, be produced at so little expense. That the cost is lessened we readily admit, because no more than seven ploughings are given through the whole Rotation; but whether the crops will be of equal value, and whether the ground will be preserved in equally good condition, are points which remain to be ascertained by experience.

Rotations in East Lothian.

In East Lothian, a district in which Agriculture has reached a high degree of perfection, the following Rotations are observed. On lands near the sea where the soil is a dry gravelly loam, a four-course shift, as they call it, is adopted. 1. Turnip with or without manure; 2. barley or Spring-wheat with grass seeds; 3. clover, used green for cattle, or cut for hay; 4. wheat, or oats if wheat was taken before, manured on the clover lay. On this description of land, the turnips are consumed on the ground by sheep. On deeper loams with a dry bottom the usual Rotation is, 1. turnips; 2. barley or spring wheat; 3. grass; 4. oats; 5. beans drilled and horse-hoed; 6. wheat. The manure is applied only once, and in this Rotation is given to the turnip, so that success in this mode of cultivation can be obtained only on land of the best quality. On heavy loams with a retentive subsoil the method is somewhat different; namely, 1. fallow with manure; 2. wheat; 3. beans drilled and horse-hoed; 4. barley; 5. clover, which is manured on the stubble; 6. oats; 7. beans; 8. wheat. The application of manure twice in the course of this Rotation is found very beneficial.

Varieties of the same grain.

Connected with Rotation we may observe that a change of the *variety* as well as of the *species* of the plants used in husbandry, is found to be attended with great advantage. It is well known that of two parcels of wheat, for example, as much alike in quality as possible, the one which had been raised on a soil differing much from that on which it is to be sown, will yield a better produce than the other that grew in the same, or in a very similar soil and climate. Thus farmers too, in one district find that wheat from another, although not superior to their own, is a very advantageous change; while oats and other grain brought from a clayey to a sandy soil, are more productive than seed raised on similar ground.

Distribution of crops.

No precise rules can be laid down for fixing the proportion of any farm which should be occupied by the different crops; for the quantity of land destined to each must be varied not only according to its soil and climate, but even according to its local situation in regard to markets. As, however, a great object in every well-regulated system of husbandry is to preserve the ground in good condition, and at the same time to derive from it the greatest quantity of produce it is capable of yielding, a certain relation must always be established between the extent of land allotted to green crops on the one hand and to corn crops on the other. The necessity of this arrangement will appear from the fact that, while the return of manure from corn is only about four tons for the acre, the amount arising from a green crop exceeds six tons; and, as it has been calculated that a farm cannot be kept at the proper pitch of fertility, unless the crop yield manure at the average of five tons, it becomes manifest that a given proportion of the land must be used for the production of turnip, clover, and potato.

Experiments on Soils and Manures.

Before we conclude this branch of the subject we shall add a few remarks on the advantage of experiments on soils and manures, made with the view of ascertaining their influence on each other, and their respective tendency to invigorate the principles of fertility, and increase the amount of Agricultural produce. Here we do not allude merely to those trials made by theorists and speculative writers on the Geological properties of soil at large, nor to those ingenious conclusions derived by the Chemist from a scientific analysis of the various substances which are applied for its improvement in the great scale. We rather mean those particular experiments which are made by individuals on their own lands, with a reference to the several kinds of manure which may happen to be within their reach. Were this plan generally adopted by farmers, a degree of precision and accuracy in their knowledge of rural affairs would soon be acquired; which, we venture to predict, would place Agriculture as far in advance of what it is at present, as it is now in advance of what it was fifty or eighty years ago. The trouble and expense of making experiments is, no doubt, considerable; but the value of the knowledge thereby obtained would prove an ample remuneration, preventing much useless labour and an unprofitable outlay of capital.

by Mr. Oliver.

To illustrate what we mean we shall give an example of the kind of experiment now recommended, supplied to us by an eminent Agriculturist in Mid Lothian.* The object in view was to ascertain, in the first place, the relative value, in producing potatoes, of dry recent horse-manure, of cow-dung, and of street-sweepings, or rather the aggregate substances which are collected in large towns under the direction of the police; and secondly, that particular distance between the rows in a field of potatoes which will secure at once the largest produce and the best quality.

For this purpose a portion of land was selected, as nearly as possible of a uniform character, and extending to about two Scotch acres. The plan of proceeding will be easily understood by the subjoined description of the field. It was divided into five portions of thirty-six feet broad; each of which again divided into three portions twelve feet broad. Upon the first twelve feet, beginning at one side of the field, twelve drills, occupying one foot each, were formed, and cow-manure applied at the rate of forty carts, weighing about eighteen hundred weight each, to the acre. Upon the second twelve feet twelve drills of the same width were made, to which the same quantity of dry horse-manure was applied; and on the third twelve feet, the like quantity of street-manure was laid, and the same number of drills were planted. In like manner, upon the remaining four divisions of thirty-six feet, drills at the distance of eighteen, twenty-four, thirty, and thirty-six inches respectively were formed, and the same kinds and quantities of manure were applied in the same order; that is, on every separate portion of thirty-six feet, subdivided into three sections of twelve feet, cow-dung, horse-dung, and street-dung were laid successively as has just been described.

The whole field was planted with that description of potato known in Scotland by the name of *Dons*, and in England by that of *Pinkeyes*. It is obvious that there were in it fifteen lots or portions; each of the five principal sections being subdivided into three minor sections. When the crop was ripe, each division was lifted separately, the produce freed from earth by riddling, and carefully weighed. In order to ascertain the effect of the different widths on quantity, the weight obtained from each of the five divisions on which drills of twelve, eighteen, twenty-four, thirty, and thirty-six inches respectively were formed, was ascertained. For this purpose it will be observed, it was not necessary to make any distinction as to the different kinds of manure applied, because each division received an equal portion of the three sorts.

The result as to the effect of distance between the drills is exhibited in the Ist Table, and goes far to prove the importance of attending to that particular.

The IId Table exhibits the result of the experiment as to the relative value of the several kinds of manure employed; which, taken in connection with various other experiments on the same subject, leaves no doubt that great benefits would arise from experimental investigations in regard to the means of fertilizing land for different species of crops. It is rendered manifest on the present occasion, that street-manure is very inferior, for the purpose of cultivating potatoes, to that supplied either by the cow or horse; but no general conclusion can be established until it shall be verified by experiments that its inferiority is equally great on all other soils. The ascertainment of this simple fact might perhaps lead to the most important results as to the peculiar food, or *pabulum*, of the potato plant.

The IIId Table is formed by taking the average produce per acre, obtained from each of the three kinds of manure employed, and at the several distances between the rows, as shown in Table II. In this way is brought into one view the comparative values of the manures and the average result of the five experiments. In fact, each of the five greater divisions may be regarded as a separate illustration of the principles involved, whether in the mode or material of cultivation; though when the whole are alternated and repeated under so great a variety of circumstances, they produce a greater degree of confidence than when estimated singly. But we beg the attention of the reader to the Tables themselves.

---

* Mr. Oliver, who through the medium of the Periodical Press has thrown much light on some interesting branches of rural economy.

Sketch of the Field showing the situation of the Lots, their Produce, and the manner in which the different kinds of Manure were applied.

Measurement.			Inches between rows.								
A.	R.	F.						BOLLS.	F.	P.	
0	1	5¾	12	Cow-dung	12 Rows	15¼ Falls	Produce	4	0	0	36 feet.
				Horse-dung	12 Rows	15¼ Falls	Produce	4	2	0	
				Street-dung	12 Rows	15¼ Falls	Produce	4	0	0	
0	1	7¾	18	Cow-dung	8 Rows	16 Falls	Produce	6	0	0	36 feet.

Results. Width of Drills.

From the Ist of these Tables it appears that the distance of thirty inches between the drills ought to be preferred to any of the others; there being uniformly a loss on all the portions grown at narrower intervals, and the greatest on that where the drills were only twelve inches apart. It appears, at the same time, that a greater width would not prove beneficial; for the piece of ground where the drills were at the distance of thirty-six inches was not equally productive with that on which they were only thirty inches separated; the profit on the latter being £1. 12s. 6d., whereas on the former it was only £1. 1s.

Comparative goodness of manure.

From the IId Table it is manifest that dry recent horse-manure is decidedly preferable to either of the other two, the loss with it on drills of twelve inches being considerably less than with the cow or street-dung: while in drills at all the other distances, it yields by far the largest profit. It further results from the facts detailed in this Table that street-manure should not be used in growing potatoes where either of the others can be procured; and on the whole it is rendered too clear to admit of any doubt in the mind of a practical Agriculturist, that the width between the rows and the kind of manure applied are objects of the greatest importance in the management of this particular crop.

On Potato Crops.

From weighing the foregoing facts it might be inferred that the growing of potatoes, even with the largest profit which appears attainable, is not an object worthy of much attention. It is admitted that the profit is very small, but it ought to be kept in mind that, at certain intervals, the land must receive a supply of manure, in order to compensate for the exhaustion occasioned by a succession of corn crops. It is equally necessary, too, that the soil shall be well pulverized and completely cleared from all root weeds; and these operations can be performed to advantage only when the field is subjected to a Summer-fallow, or cropped with drilled potatoes or turnips. Besides, in estimating on the cost of production in the foregoing Tables we have charged the crop with the whole cost of manure together with the expense of sufficiently pulverizing the ground so as to warrant the expectation of at least three good crops without any more dung, or much outlay on the process of clearing. On grounds of a moderately light texture, potatoes are a better preparation for wheat than Summer-fallowing; and hence whatever profit is gained by the green crop ought to be regarded as in some measure, a gratuitous addition to the farmer's capital.

CHAPTER II.

On Live Stock.

Divisions of the subject.

We have already remarked that Rural Economy divides itself into two great heads: first, the cultivation of the soil for vegetable productions; and, secondly, for the rearing of live stock. This last is naturally separated into three parts, as it respects the objects which are kept in view in the breeding of cattle, whether for labour, the butcher-market, or the dairy. According to the order thus suggested, therefore, we shall arrange our observations on the subjects which are usually comprehended under the title placed at the head of this Chapter.

Animals for labour. The Horse.

On many accounts, the Horse deserves to stand at the head of domestic animals. Viewed as the assistant of Man in the labours of the field, he is chiefly valued for his strength, activity, and hardiness. Mr. Culling, whose Work *On Live Stock* is greatly esteemed, describes the Horse best fitted for Agricultural purposes in the following terms. "His head should be small as the proportion of the animal will admit; his nostrils expanded and muzzle fine; his eyes cheerful and prominent; his ears small, upright, and placed near each other; his neck rising out from between his shoulders with an easy tapering curve must join gracefully to the head; his shoulders being well thrown back, must also go into his neck, at what are called the points, unperceived, which perhaps, facilitates the going more than the narrow shoulder; the arm, or fore thigh should be muscular, and tapering from the shoulder, meet with a fine, straight, sinewy, bony leg; the hoof circular, and wide at the heel; his chest deep and full at the girth; his loin or fillets broad and straight, and body round; his hips or hooks by no means wide, but quarters long, and tail set on so as to be nearly in the same right line as his back; his thighs strong and muscular; his legs clean and fine-boned; his leg bones not round, but what is called lathy or flat.

Welsh and Highland Ponies.

If we trace the lineage of this noble animal, we shall probably find the true type of his ancestors still existing in the ponies of Wales and Scotland. The Highland horse is sometimes only nine, and seldom twelve hands high, except in some parts of the Hebrides, where, by selection and better feeding, the size has been raised to thirteen or fourteen hands. The best of this breed are handsomely shaped, have small legs, large manes, little, neat heads, and are extremely active and hardy. The Welsh horse bears a near resemblance to the larger description of the Highland breed, and is still more remarkable for the power of enduring fatigue. The modern system of Agriculture, however, which has introduced almost everywhere the two-horsed plough, has gradually superseded all attention to the native species of the country. The Shetland pony, indeed, is sometimes reared as a curiosity, or for the use of children, but in no part of the Kingdom for the purposes of tillage. This ancient race is supposed to have been brought into Scotland from Scandinavia, when the Northmen first gained a footing in Caledonia; and it is precisely the same breed which subsists at present in Norway, the Feroe Isles, and Iceland, being totally distinct from all the varieties which are seen on the Continent of Europe Southward of the Baltic.

Dutch and German horses.

The main source of improvement in our farm horses may be traced to Holland and Germany, whence our Agriculturists at an early period imported a breed of heavy, large-boned animals, the parents of the finest and best working animals we at present possess, whether in the South or North. The *Suffolk Punch* is perhaps better suited than any other to the general purposes of rural labour; having a great deal of constitutional hardiness, combined with sufficient action for either the plough or the waggon. The colour, usually yellowish or sorrel, with a white scratch or blaze on the face; the head large, ears wide, muzzle coarse, fore end low; back long, but very straight; sides flat; shoulders too far forward; hind-quarters rather high about the hips; legs round and short in the pasterns; deep-bellied and full in the flanks, a quality which enables him to retain his food long, and undergo without inconvenience a more protracted toil than a finer horse could endure.

Suffolk Punch.

Black Cart-horse.

The *Black Cart-horse*, so well known in most parts of England, and of which we see the most improved variety in the streets of London, is not so much esteemed by the farmer as by the drayman and the waggoner. He is heavy and sluggish, and by no means so capable of standing a long day's work as a much smaller animal of better blood.

Cleveland Bay.

The *Cleveland Bays* are a more active and hardy race, though it is alleged, they are no longer so carefully reared as in former times. They are said to have drawn their best qualities from a cross with racers, and, consequently, to have turned out excellent hunters, good roadsters, and, at the same time, well fitted for the duties of our Cavalry regiments. In the Northern Counties, they are to be seen in a condition more or less improved, on almost every farm, both as plough-horses, and also as prepared for the market, where they are eagerly purchased by coachmasters and travellers.

Clydesdale horse.

The *Clydesdale horse* is in great repute in several Counties on both sides of the border, and for the uses of Agriculture he is probably equal to any other in Britain. He is larger than the *Suffolk Punch*, and the neck is somewhat longer; the colour is black, brown, or grey, and a white spot in the face is esteemed a mark of beauty. The breast is broad; the shoulder thick; the hoof round, usually of a black colour, and the heels wide; the back straight and broad, but not too long; the hucks visible, but not prominent, and the space between them and the ribs short; the tail heavy and well-haired; and the thighs full and muscular. He is in general very true to his work, and remarkably steady in the draught.

Into the minute points of breeding and rearing we cannot enter with any prospect of satisfying the professional reader, or even of gratifying the curiosity of such as may choose to study this subject solely for amusement. We therefore satisfy ourselves with a reference to the Works of Lawrence, Marshall, Culley, Parkinson, Clark, Coventry, and to a volume lately published in the *Farmer's Series* of the *Library of Useful Knowledge*, where the most accurate information is given relative to every thing which respects the history and treatment of the Horse. Confining ourselves to the use of that animal for Agricultural labour, we may advert to the question which has been sometimes started among practical men, whether oxen might not be beneficially substituted for horses in all the ordinary processes of Husbandry. In point of economy, then, it has been maintained that the ox is decidedly preferable to the horse, for besides that he can be more cheaply fed, he may, after serving a few years as a labourer, be remitted to the stall and fed for the butcher. It is admitted, at the same time, that wherever a powerful and steady pull is required, the ox performs the work better than his rival, being more patient and equal in his movements, and proceeding generally at a slower step. On this account a plough drawn by oxen would be selected in preference to any other by the farmer who has tough swards to tear up, or very rough ground to cultivate; and for the same reason these animals are yoked in the threshing-machine, whenever it is of any consequence to have a sure and regulated motion communicated to it. But, on the other hand, the ox is nearly useless for all other kinds of farm labour. He is not suited to the cart or waggon even on our fields, and far less on our public roads. Besides, he cannot be stirred to any unwonted exertion, however urgent may be the wants of his master; for if he is pushed beyond his natural step, all his energies forsake him, and he either stands still or throws himself on the ground. In rude Ages, when only the coarser productions of the soil are in demand, the cultivator uses the animal which cost him least in rearing and feeding; but whenever the progress of civilization extends the variety of commodities required by the consumer, and gives a value to luxuries in proportion to the early season at which they can be obtained, he dismisses the slow-paced ox, and adopts in his stead the more energetic horse. This is the natural order of things as soon as green crops constitute an article in the regular course of farming. On the Continent, where oxen continued to be used a considerable time after they were generally superseded in Britain, the horse is now almost universally preferred. The French Agricultural Writers agree with those of Britain, in perceiving the many advantages which attend the employment of the latter. A more enlightened experience every day tends to confirm the choice; and in the course of a few years the labour of the ox will be altogether unknown, except in particular situations where the greater vivacity and swiftness of the horse might prove hazardous. We conclude this section by remarking that the care bestowed upon the keeping of the horse is always well repaid. The manure replaces the expense of litter; and his constant aptitude for work is an ample equivalent for the carrots, potatoes, and grain, which constitute his best food.

Comparison betw. horses and oxen.

Of Cattle.

There are now numerous varieties or breeds of cattle in Great Britain, but perhaps all of them may be traced more or less directly to that singular one which is still preserved as a curiosity in the parks of several Noblemen, more especially Lord Tankerville and the Duke of Hamilton. It is usually distinguished as the *wild*, or original breed, and has been described by Mr. Culley in the Work already mentioned. Their colour, says he, is invariably of a creamy white; muzzle black; the whole of the inside of the ear, and about one-third of the outside from the tips downward red; horns white with black tips, very fine, and bent upwards; some of the bulls have a thin, upright mane, about an inch and a half or two inches long. The weight of the oxen is from thirty-five to forty-five stone, and of the cows from twenty-five to thirty-five stone, the four quarters, fourteen pounds to the stone. At the first appearance of any person they set off in full gallop, and at the distance of about two hundred yards make a wheel round and come boldly up again, tossing their heads in a menacing manner. On a sudden they make a full stop at the distance of forty or fifty yards, looking wildly at the object of their surprise; but upon the least motion being made they all turn round and fly off with equal speed, but not to the same distance, forming a shorter circle, and again returning with a bolder and more threatening aspect than before. This time they approach much nearer, probably within thirty yards, when they again make another stand, and again fly off. They repeat this movement several times, shortening their distance, and advancing nearer and nearer till they come within such a short distance that most persons think it prudent to leave them, not choosing to provoke them further.

Wild cattle.

Mode of killing them.

The mode of killing them was perhaps the only modern remains of the grandeur of ancient hunting. On notice being given that a wild bull would be killed on a certain day, the inhabitants of the neighbourhood came mounted and armed with guns sometimes to the number of one hundred horse and four or five hundred foot, who stood upon walls or got into trees, while the horseman rode off the bull from the rest of the herd, until he stood at bay, when a marksman dismounted and fired. At some of these huntings thirty or forty muskets have been discharged before he was subdued. On such occasions the bleeding victims grew desperately furious from the smarting of his wounds and the shouts of savage joy that were echoing from every side. But from the number of accidents that happened, this dangerous mode has been little practised of late years; the park-keeper alone generally killing them with a rifled gun at one shot.

Habits of cows after calving.

When the cows calve they hide their young for a week or ten days in some sequestered situations, whither they go to suckle them two or three times a day. If the calves are approached by any person, they clap their heads close to the ground, and lie like a hare in form to conceal themselves. This is a decided proof of their native wildness; and if they are actually disturbed, they attack the assailant with the utmost fury, pawing and bellowing like an incensed bull. It is remarkable, too, that when any one of the herd happens to be wounded, or has grown weak and feeble through age or sickness, the rest set upon it and gore it to death.

Devonshire breed.

Hereford and Sussex.

Dutch.

The *Devonshire* breed is said to be directly descended from this race, of which the best specimen is seen at Chillingham Park in Northumberland. The resemblance in in some points is very striking; but the animals are of a light red colour and rather small in size. The *Hereford* and *Sussex* cattle are nearly of the same colour, and in other respects possess similar properties, but are decidedly better milkers. The *Dutch*, or *short-horned* description, which are much esteemed in the Eastern Counties, yield a large quantity of rich milk and butter, fatten readily, though they are on the whole of a delicate constitution. **Lancashire.** The *Lancashire* breed is distinguished by long horns, thick hides, long close hair, coarse necks, and large hoofs; they are of various colours, but generally have a white streak along the back, and though they are not remarkably productive, they enjoy a hardy constitution. **Ditchley.** The celebrated *Ditchley* breed is an improved variety of the Lancashire, being smaller and cleaner boned; they fatten well, but are not very highly valued by the dairyman as milkers.

Galloway. Besides the varieties now mentioned, there is the *polled* or *hornless* kind, the most esteemed of which are found in *Galloway*, a district in the South-West of Scotland. The true Galloway bullock is straight and broad on the back, and nearly level from the head to the rump; broad at the loins, not however with hooked bones or projecting knobs; so that when viewed from above the whole body appears beautifully rounded like the longitudinal section of a roller. He is long in the quarters, deep in the chest, short in the leg, and moderately fine in the bone. The prevailing colour is black or dark-brindled. Like the Devonshire ox, he is rather undersized; though when well fed he has been known to weigh about a hundred stone.

Cross of the Galloway. Dr. Coventry alleges that it is not more than seventy or eighty years since the Galloways were all horned, and very much the same in external appearance and character with the breed of black cattle which prevailed over the West of Scotland at that period, and which still abound in perfection, the large-sized ones in Argyleshire, and the smaller in the Isle of Skye. The Galloway cattle at the time alluded to were coupled with some hornless bulls, of a sort which do not now seem to be accurately known, but which were then brought from Cumberland; the effects of which crossing were thought to be the general loss of horns in the former, and the enlargement of their size; the continuance of a hornless sort being kept up by selecting only such for breeding, or perhaps by other means, or by the practice of eradicating with the knife the horns in their very young state.

Suffolk duns. The *Suffolk duns* are, according to Mr. Culley, nothing more than a variety of the breed now described, and differing only in colour. **Ayrshire.** The *Ayrshire* cow is a valuable animal, as the milk it affords, although not very abundant, is uncommonly rich, and is given with very little interruption throughout the whole year. **Kylocs.** The Highland *Kylocs*, as they are sometimes denominated, are in great request in the Southern Counties, on account of the delicate nature of their flesh. **Norlands.** This is supposed to be a different breed from the *Norlands*, or such as are reared in the remote districts of Ross, Sutherland, and Caithness. **Orkney and Shetland.** The Islands of *Orkney* and *Shetland* produce a very diminutive species of cattle, some of them not weighing more than two hundred pounds; but they feed well, and when brought to good condition in the meadows of the South, they bring in the market a remunerating price. **Welsh.** Of *Welsh* cattle there seems to be two distinct kinds. The large sort are of a brown colour, with some white on the rump and shoulders, denoting a cross from the *long horns*, though in shape bearing no resemblance to them. They are long in the legs, stand high in proportion to their weight, are thin in the thigh, and rather narrow in the chine; their horns are white and turned upwards; they are light in flesh, and, next to the Devons, well-formed for the yoke, have very good hoofs, and walk lightly and nimbly. The other sort are much more valuable; colour black, with very little white; of a good useful form, short in the leg, with round, deep bodies; the hide is rather thin, with short hair; they have a lively look and a good eye; and the bones, though not very small, are neither large nor clumsy; and the cows are considered good milkers.

Choice for breeding. From a reference to the statements just made, it appears manifest that the improvement of the lower animals in form and value depends very much on the care of the breeder. In rearing live stock of all descriptions, it ought to be an invariable rule to select for parents such as are small-boned, straight-backed, smooth-skinned, and round-bodied, with clean necks, small heads, and little or no dewlap. Those, too, which are of a quiet and docile manner ought to be preferred, as they generally require less food, and are more easily fattened. Nor should the stock-farmer overlook the valuable quality of becoming early mature; a point in which the different breeds of cattle vary to a considerable extent. In the management of cows which are kept for breeding it is to be observed, that about a month or six weeks previously to the time of calving, they ought to be abundantly supplied with the richest kind of food; for it is found that by this treatment, a larger quantity of milk is obtained than when they are fully fed for a longer period.

Rearing. Mr. Marshall informs us that the method pursued for rearing calves in the Midland Counties is this: they are allowed to suck for a week or a fortnight according to their strength; they then have new milk in the pail for a few meals; next new milk and skim-milk mixed, a few meals more; then skim-milk alone, or porridge made with milk, water, and ground oats, and sometimes oil-cake until cheese-making commences; after which, whey-porridge, or sweet whey in the field; being careful to house them in the night until warm weather be confirmed. The treatment of young cattle from the time they are separated from their dams, or are able to subsist on the common food of the other stock, must depend upon the circumstances of the farm on which they are reared. In Summer their pasture is often coarse but abundant; and in Winter all good breeders give them an allowance of succulent matter together with straw or hay. Speaking of the short-horned variety, Mr. Culley remarks, that the first Winter they have hay and turnips; the following Summer coarse pasture; the second Winter straw in the fold-yard, and a few turnips once a day in an adjoining field, just sufficient to prevent the straw from binding them too much; the next Summer tolerably good pasture; and the third Winter as many turnips as they can eat, and in every respect treated as fatting cattle.

For the butcher. The farmer who feeds for the butcher-market has three separate methods to pursue; all of which will answer his purpose in certain circumstances, and his choice must be determined by the nature of his land, as well as by the main object which he had in view when he rented it. Live stock may be fattened on pasture ground, by *soiling* in proper yards or sheds, where they are supplied with abundance of green food; or lastly in the stall, where they are furnished with turnips, cabbages, and other succulent vegetables, combined with various descriptions of dry meat. The practice of pasturing cattle is the most natural and the most simple; and the owner can hardly go wrong, if he provide the animals with pure water and a sufficient shelter during the heats of Summer. Soiling is regarded by most feeders as preferable to the other; even taken by itself, and more especially if connected with the general purposes of husbandry, the improvement of the fields, and the increase of corn produce. By this mode, too, the beasts are better protected both from insects and the weather; the food is consumed with less waste; and when the yards are suitably furnished with litter, a large supply of excellent manure is obtained. In this case, as in all others, due attention must be paid to the supply and quality of the water, as nothing contributes more to the health of young stock. The approach of Winter usually suggests the expediency of stall-feeding, as both warmth and cleanliness are essential to the accomplishment of this object. Besides, the cattle are kept more quiet and free from interruption, and are found in such circumstances to take in flesh more quickly. The food employed for this purpose consists of turnips, potatoes, carrots, cabbages, oil-cake, oats, barley-meal, beans, with different kinds of straw, cut small by means of machinery. The moist and dry food should be given in such proportions as to prevent any injurious effect on the digestive organs.

Desiderata.

It has been remarked, that notwithstanding the high perfection to which certain breeds of cattle have been brought in Britain, and the great attention paid to every part of their management, several interesting points, which should be taken into calculation, remain still to be determined. Our knowledge, for example, is very incomplete in regard to the precise degree of nutriment afforded by different kinds of herbage and roots; the quantity of food consumed by the different breeds in proportion to the time of fattening and increase of weight; and the advantage of selecting the large or smaller varieties in any given circumstances of climate and produce. There is, no doubt, in every district a certain practical feeling which directs the stock-farmer in the choice of his cattle, and in the adaptation of means to the end, which he has in view; but, it is true, at the same time, that no successful attempt has been made to reduce such maxims to general principles, or to render the experience of one available to all.

Of Sheep.

Different breeds.

Next to cattle, Sheep in many parts of the Country are esteemed a valuable stock, the whole income of the farmer being derived from their milk, wool, and flesh. The numerous breeds of this animal are usually arranged into two classes: those which yield the *short* wool, and those which yield the *long*, or, as it is frequently described, the *combing* wool. To these, some writers have added the *mountain* breed; but so far as the wool is regarded as a characteristic, there is no room for this distinction. The first of these classes, however, including the one just stated, comprehends the varieties which are reared in the hilly districts of Wales, the North of England, and the Highlands of Scotland; the second embraces those which appear in Hereford, Dorset, Sussex, Norfolk, and some other places; and the last, or long-woolled, include the varieties which occupy the richer and more fertile vales of the Kingdom, and are known as natives of Leicestershire, Lincolnshire, and the banks of the Tees.

Mountain. Cheviot.

The *mountain* sheep are distinguished by having black faces and legs, as well as large spiral horns. They are a very hardy race, and afford a delicate, well-flavoured mutton, though their wool is coarse and shaggy. The *Cheviot* breed, which likewise belongs to this class, has no horns; the face and legs are commonly white, and the eyes have a lively expression. The wool in this case is better than either the Welsh or Highland, and the animal is remarked as a good feeder, though the meat is not so highly valued in the market.

Herefordshire. Ryelands. South Downs. Norfolk.

The second class, or *Herefordshire*, are comparatively small, have no horns, white legs and faces, and exhibit a fine short wool. They are also known by the name of *Ryelands*. It has been observed of this description of stock, that they can subsist on less food than any other, and are remarkable for abstinence, and even for the endurance of hunger. The *South Downs* are also distinguished for the shortness and fineness of their wool, as well as by having grey faces and legs, small long necks, and affording a fine-grained, delicious mutton. This breed prevails in the dry, chalky grounds of Sussex. The *Norfolk* breed have a great resemblance to the Welsh or Scotch; having a black face, large spiral horns, short wool, and affording well-flavoured meat.

Old Leicester. New Leicester. Ditchley.

The long-woolled sheep are familiarly known by the names of *Lincolnshire*, or *Old Leicester*, and are distinguished by the want of horns, by their white faces, long, thin, and weak bodies, large bones, coarse mutton, and by having wool from ten to eighteen inches in length. This breed thrives only in the richest pastures, and is chiefly valuable on account of its wool. But it is from them that the *New Leicester*, or *Ditchley* breed is descended; a name derived from the place at which it was so much improved by the care and skill of the celebrated Mr. Bakewell. These animals attract attention by their lively eyes, fine heads, straight backs, barrel-shaped bodies, small bones, and a disposition to fatten at an early age. The weight of the quarter in ewes of three or four years old, is from eighteen to twenty-six pounds; in two years old wethers, from twenty to thirty pounds; and the length of wool varies from six to fourteen inches.

Teeswater.

The main excellence of this breed consists in their fattening more speedily, and on a smaller quantity of food, than any other; in their having a larger proportion of meat on an equal weight of bone; in the superiority of the meat itself both as to texture and flavour; in their valuable wool; in being ready for the market early in Spring; and in bringing, of consequence, a larger profit to the farmer. The *Teeswater* variety have longer legs, finer bones, and a thicker and firmer carcass than the Lincolnshire; the mutton is better and finer grained, and the wool is shorter and less heavy. This is the largest breed in the Island, and is the most common in the rich meadows bordering on the river whence it derives its name. But, unfortunately, it seems to be calculated only for warm, well-sheltered pastures, and cannot therefore be transferred to the Cheviot range, or the still more exposed mountains of the Highlands, where its value would be duly appreciated. Besides, it requires to be fed abundantly in severe Winters, an attention which could not be conferred upon it in a hilly country, or in the extensive sheep-walks of Wales or Argyle.

Romney-marsh.

There is also a variety, which bears among breeders the designation of the *Romney-marsh*, and which possesses many good properties. It has no horns; the face and legs are white; the body rather long, but well-shaped, and the bones somewhat large. The wool, however, is excellent, having a considerable length, and a beautiful colour. Like the Teeswater breed, it requires rich pasture, and a greater degree of care than can be bestowed by the stock-farmer on upland grounds.

Hardwick.

The *Hardwick* sheep are peculiar to that rocky district whence flow the Duddon and the Esk, in the County of Cumberland. They are without horns, have speckled faces and legs, short wool, which, though not by any means fine, is greatly superior to that produced by the heath or mountain sheep, properly so called.

Dun-faced.

Shetland.

The *Dun-faced* breed seems to have been imported into Scotland from Norway or Denmark at a very early period, and is still found in most of the Counties beyond the river Forth, though not in large numbers. Of this ancient race there are now several varieties produced, as usual, by peculiarities of situation and different modes of management. In *Shetland*, it would appear, there are two varieties of the sheep, one of which is considered aboriginal, and bears very fine wool; but the number of these is much diminished, and in some places they have been entirely supplanted by foreigners. The other variety carries coarse wool above, and fine, soft wool below. They are said, moreover, to have three different successions of wool yearly, two of which have a greater resemblance to long hair, and are termed by the common people *fors* and *scudda*. When the wool begins to loosen in the roots, which generally happens about the month of February, the hairs or *scudda* spring up; and when the wool is carefully plucked off, the tough hairs continue fast until the new wool grows up about a quarter of an inch in length, when they gradually wear off; and when the new fleece has acquired about two months' growth, the rough hairs, termed *fors*, spring up and keep root until the proper season for pulling them arrives, when they are plucked off together with the wool, and separated from it at dressing the fleece by an operation called *forsing*. The *scudda* remains upon the skin of the animal, as if it were a thick coat; a fence against the inclemency of the seasons which provident Nature has furnished for supplying the want of the fleece in a high and stormy latitude. The wool is of various colours; the silver grey is thought to be the finest; but the black, the white, and the brown are very little inferior; though the pure white is certainly the most valuable for all the finer purposes in which combing wool can be used.

Merino.

Our catalogue would be incomplete did we not mention the *Merino*, which, though not a native of Britain, has already acquired considerable importance. This sheep was brought into England in 1788, but did not excite much interest till the year 1804, when George III. began his sales. The patriotic object contemplated by His Majesty of spreading them widely over the Country and subjecting them to the experiments of the most eminent professional breeders, has been in a great measure accomplished by the institution of the *Merino Society*, which includes among its Members some of the greatest landholders in the Kingdom. For some years past, however, this breed, notwithstanding all the care bestowed upon it, is acknowledged to have been on the decline; and we may add, that it has succeeded best in those cases where it was judiciously crossed with a native variety, without any attempt to preserve it pure.

Merino fleeces.

Every one knows that the Merino is chiefly valued for its uncommonly fine fleece, which upon the average weighs from three to five pounds. In colour it is unlike that of any English breed. There is in the surface of the best Spanish fleeces, a dark-brown tinge approaching to black, which is occasioned by dust adhering to the greasy properties of its pile; and the contrast between this tinge and the rich white colour below, as well as that rosy hue of the skin which denotes high proof, excites, at first sight, no little surprise. The harder the fleece is, or, in other words, the greater resistance it makes to the pressure of the hand, the finer is the wool esteemed; here and there, indeed, a fine pile may be found in an open fleece, though this occurs but rarely. Nothing, however, tends to render it more unsightly to the English eye than the large tuft of wool which covers the head: it is of very inferior quality, and is ranked with what is produced on the hind legs; on which account it does not sort with any of the three classes; *viz.* the *rafinos*, or prime; *finos*, or second best; and the *terceros*, or third, and of course is never exported from Spain.

Carcasses.

Among the Merinos, the male has horns, the female none, or very rarely; the faces and legs are white, and the bones fine. The average weight per quarter of a tolerably fat ram is about seventeen pounds, and that of a ewe about eleven pounds. The shape, if we take the ideas of English breeders for a standard, is far from perfect. The pendulous skin beneath the throat, which is usually accompanied with a sinking or hollowness in the neck, is accounted a deformity here, though in Spain it is much esteemed, as denoting both fine wool and a heavy fleece. Yet the Spanish sheep, generally speaking, are level on the back and behind the shoulders; and Lord Somerville has proved that there is no reason whatever for connecting the peculiarity of form just mentioned with the amount or quality of wool.

Works on breeding.

Experiments on the different sexes.

We cannot enter upon the extensive subject of breeding, considered in a professional point of view; holding it enough to refer such readers as are desirous of full and accurate information to the Treatises of Dr. Parry, Sebright, Culley, Sir John Sinclair, Mr. Johnston, the *General Report of Scotland*, the Work of Mr. Bakewell; Marshall's *Rural Economy*; the *Farmer's Calendar*; *Communications to the Board of Agriculture*; the *Middlesex Report*; and to a variety of able Essays in the *Quarterly Journal of Agriculture*. We shall, notwithstanding, quote from the last of these publications a notice relative to a "method of obtaining a greater number of one sex at the option of the proprietor, in the breeding of live stock." The Essay, at length, is to be found in the *Annales de l'Agriculture Française*, and is worthy of attention, as containing the details of some interesting experiments made with the view just stated. M. Girou proposed, at a meeting of the *Agricultural Society of Séverac*, on the 3d of July, 1826, to divide a flock of sheep into two equal parts, so that a greater number of males or females, at the choice of the proprietor, should be produced from each of them. Two of the Members of the Society offered their flocks to become the subject of his experiments, and the results communicated were, to some extent, in accordance with the author's expectations.

The first experiment was conducted in the following manner. He recommended very young rams to be put to the flock of ewes from which the proprietor wished the greater number of females in their offspring; and also that during the season when the rams were with the ewes they should have more abundant pasture than the other; while to the flock from which the owner wished to obtain male lambs chiefly, he recommended to put strong and vigorous rams, four or five years old. The following Tabular view contains the result of this experiment.

Flock for Female Lambs.

Age of the Mothers.	Sex of the Lambs.	
	Males.	Females.
Two years.........	14	26
Three years........	16	29
Four years........	5	21

Five years and older	18	8
Total..	53	84

N. B. There were three twin births in this flock. Two rams served it, the one fifteen months, the other nearly two years old.

Flock for Male Lambs.

Age of the Mothers.	Sex of the Lambs.	
	Males.	Females.
Two years	7	3
Three years........	15	14
Four years.........	33	14
Total..	55	31
Five years and older	25	24
Total..	80	55

N. B. There were no twin births in this flock. Two strong rams, one four, the other five years old, served it.

The second experiment is thus related by the author. "During the Summer of 1826, M. Cournejouls kept upon a very dry pasture, belonging to the village of Bez, a flock of 106 ewes, of which 84 belonged to himself, and 22 to his shepherds. Towards the end of October, he divided his flock into two sections of 42 heads each, the one composed of the strongest ewes, from four to five years old; the other of the weakest beasts, under four or five years old. The first was destined to produce a greater number of females than the second. After it was marked with pitch in my presence, it was taken to much better pasture behind Panouse, where it was delivered to four male lambs, about six months old, and of good promise. The second remained upon the pasture of Bez, and was served by two strong rams, more than three years old. The ewes belonging to the shepherds, which I shall consider as forming a third section, and which are, in general, stronger and better fed than those of the master, were mixed with those of the second flock. The result was that the

	Males.	Females.
First section gave	15	26
The second	26	14
The third	10	12
In the first section there were two twin births	0	4
In the second and third there were also two......................	3	1

Apparent general law.

Besides these very decisive experiments, M. Girou relates some others made with horses and cattle, in which also his success in producing a greater number of the one sex than of the other appears. The general law, so far as we are able to detect it, seems to be, that when animals are in good condition, plentifully supplied with food, and kept from breeding as fast as they might do, they are most likely to produce females. Or, in other words, when a race of animals is in circumstances favourable to its increase, Nature produces the greatest number of that sex which, in animals that do not pair, is most efficient for increasing their numbers. But if they are in a bad climate, or on stinted pasture, or if they have already given birth to a numerous offspring, then Nature produces more males than females. Yet perhaps it may be premature to deduce any general law from experiments which have not yet been sufficienly extended.

Swine. Berkshire. Chinese. Gloucestershire. Hampshire. Northamptonshire. Rudgewick. Woburn. Highland or Irish.

Among the live stock produced on farms we must not omit *Swine*, of which there are numerous varieties reared in Great Britain. The *Berkshire* breed is of a reddish colour, with short legs, large ears, and a thick, compact, well-formed body; is readily disposed to fatten, and grows to a large size; but the supply of food must be constant and abundant. The *Chinese* or *black* breed is of small size, short legs, and of a good make; is considered one of the most profitable in the country; the flesh is delicate, and it fattens freely even on indifferent food. The *Gloucestershire* variety is white, and of a large size, the form not symmetrical, and in other respects not highly esteemed among feeders. The *Hampshire* breed is also white, attains a large bulk, and fattens readily. The *Northamptonshire* is remarkable for the enormous length of its ears, is of great size, but does not fatten easily. The *Rudgewick* breed takes its name from a village situated on the confines of Surrey and Sussex; it is a valuable variety because it not only grows well, but also fattens at small expense. The *Woburn* breed was introduced by the late Duke of Bedford; it is usually spotted, though the colour is various; the size is large, and it fattens so well that it attains nearly twice the weight of other hogs in the same space of time. The *Highland* or *Irish* variety is described as an inferior, animal being small and ill-shaped, and, at the same time, difficult to fatten, or otherwise to improve in its marketable value.

Sussex. Cheshire. Suffolk. Shropshire. Scotch. Hebridean.

It is worthy of notice that Mr. Culley mentions only three breeds of Swine, the Berkshire, the Chinese, and the Highland or Irish; while other writers have found a distinct breed in almost every County of England. In addition to those already described, there is the *Sussex* pig, which is distinguished by being black and white, but not spotted; it grows to the weight of eighteen or twenty stone. To these we may add the *Cheshire*, the *Suffolk*, and the *Shropshire*. In Scotland little progress has hitherto been made in the improvement of this stock, if we except the Counties of Dumfries and Galloway. The prevailing breed is of a white colour: they have light carcasses with bristles standing up from nose to tail, long legs, and are very slow feeders at any age. In the *Hebrides*, the breed, supposed by Dr. Walker to be the aboriginal, is of the smallest size, neither white nor yellow, but of a uniformly grey colour, and shaggy, with long hair and bristles. They graze on the hills like sheep; their sole food is herbage and roots, on which they live the whole year round, without shelter, and without receiving any other sustenance. In Autumn, when they are in the best order, their meat is excellent, and obtained without any artificial feeding; but when driven to the low country they fatten readily, and grow to a considerable size.

Profits of Swine. Notwithstanding the extent to which Swine are reared, it still remains a disputed point among Agriculturists whether the breeding and fattening of that species of stock, beyond the mere offal of the farm, has ever been rendered a remunerating branch of rural economy. On every establishment there is a great deal of stuff, roots, herbage, and waste corn, which would otherwise be lost; and hence it is manifest that, so far as the use of these articles is concerned, the pig must be a profitable animal. But it is, nevertheless, very doubtful whether, on fertile lands, any portion of the crop could be so applied as to place the breeding of Swine on the same footing, as to revenue and other advantages, as that of cattle and sheep. It has been calculated that, with proper management, on a farm of three hundred acres, of which two hundred are kept in tillage, an annual profit to the amount of £100 might be secured by rearing pigs; though it is admitted by the same author that, as soon as this stock exceeds the quantity of superfluous produce on which it is usually maintained, it ceases to be in any respect beneficial. The reader will find many useful observations on this branch of the subject in Culley's Work already mentioned; the *Complete Grazier*; Henderson *on Swine*; the *Farmer's Magazine*; and the *General Report of Scotland*.

On the Dairy.

We remarked at the commencement of this division that live-stock are raised not only for their flesh and labour, but also for their milk. In some parts of the country a large proportion of land is devoted to this object, and the rents of the farmer, as well as the affluence of the proprietor, are derived from the manufacture of milk in its various forms of butter and cheese. **House,** It is recommended by practical persons that the building meant for the several processes of the dairy should be erected in a cool situation, and protected from the direct approach of the solar rays, and even of a current of air varying much in temperature. The utmost cleanliness, too, is altogether indispensable. The house should be paved with stone or brick, having a gentle inclination so as to be readily dried, and the floor should be washed every day during Summer. To preserve the air cool, or at least of an equal temperature, it has been thought advisable to admit a small stream of water into the apartments, or even to be poured like a cascade from the ceiling. **and utensils.** The utensils, which are commonly of wood, ought to be cleansed with the greatest care; or if metallic, or glazed earthen vessels be substituted, they should be daily plunged into hot water, scoured with salt, and well dried before they are filled with milk. Cast-iron dishes, enamelled or fluted with tin, have been lately introduced into some dairies, and are found to answer well, both on account of their cleanliness and durability.

Care in milking. It is known to every one that the quality of milk is much affected by the nature of the food on which the animal is fed; but it is not so generally understood that the quantity depends a good deal on the mode of milking. If any difficulty occur in conducting this operation the cow should never be treated harshly, as it more frequently proceeds from pain than from obstinacy of temper. The hardness of the udder will in general denote whether there be any obstruction; in which case fomentations, together with gentle friction, ought to be used, until the flow of milk be restored. In Summer, cows ought to be milked at three equal intervals in the course of twenty-four hours; by which means the quantity is increased without deteriorating its essential properties of richness and flavour. The depth of the vessels into which the milk is poured, should not exceed three inches; and should any peculiarity of taste be occasioned by the nature of the food, it may be removed by boiling two ounces of nitre in a quart of water, and plunging about a teacup-full of the mixture into a pail of the warm milk. Those who are particular in the manufacture of butter and cheese, keep the milk of every cow separately, so as to discriminate their respective qualities, and avoid all improper combinations. With the same view care is taken that the cattle shall not be hastily driven from the field to the dairy, and that the milk shall not be much agitated or shaken in the pails after it is drawn; for in either case the liquid acquires a tendency to acidity which soon renders itself perceptible in the finer kinds of butter.

Churning. Of late years the resources of mechanical invention have been applied to lighten the labour and facilitate the object of churning. It has been found, however, that the chief secret in the management of this process, whatever be the form of the apparatus employed, is to continue the agitation with the same regular, uniform, uninterrupted motion from the beginning to the end; because it is suspected that a too rapid or unequal motion communicates to the butter a bad flavour in Summer, while, in Winter, it endangers the success of the operation altogether. A table-spoon-ful of distilled vinegar, added to the cream after it has been a considerable time moved, has occasionally proved beneficial in separating the butter, after other means had appeared to fail.

Experiments on temperature. A few years ago some interesting experiments were made by Dr. Barclay, a well-known Physiologist, and another professional gentleman at Edinburgh, with the view of ascertaining the temperature at which butter can be best procured from cream. The results were communicated to the *Journal of Agriculture*, from which we abridge the following particulars. In the first experiment fifteen gallons of cream were put into the churn at the temperature of 50° Fahrenheit; the weight per gallon having been previously ascertained to be eight pounds four ounces. By agitating the cream in the usual manner for the space of two hours the temperature rose to 56°; at the end of the churning, being four hours from the commencement of the operation, the temperature was found to be 60°, or 10° higher than at the beginning. The quantity of butter obtained in this process was twenty-nine pounds and a half avoirdupois, or nearly two pounds of butter for every gallon of cream put into the churn. The butter appeared to be of the very best quality, being firm, and rich and pleasant to the taste. A gallon of the churned milk being carefully weighed, gave eight pounds nine ounces, being an increase in weight of eight ounces per gallon above that of the cream used in this experiment.

In the second experiment, fifteen gallons of cream were put into the churn at the temperature of 55°, the weight per gallon being eight pounds two ounces. By agitating the cream as formerly, for one hour and a half, the temperature rose to 60°: at the end of the churning, being three hours and fifteen minutes from the beginning of the operation, the temperature had increased to 65°. The quantity of butter was twenty-nine pounds four ounces, and not sensibly inferior to that obtained in the first process.

A third experiment was performed, in which the same quantity of cream was put into the churn, at the temperature of 58°, the weight per gallon being eight pounds two ounces. At the end of one hour's churning the temperature had risen to 63°; and at the end of the process, which lasted three hours, the temperature was found to be 67°. The quantity of butter obtained by this experiment was twenty-eight pounds, and in quality it seemed to be rather inferior to that produced in the two former, being rather soft and spongy.

The fourth experiment was performed on the same quantity of cream, the temperature being 60°, and the weight per gallon eight pounds one ounce. During the process of churning the temperature increased as formerly; and at the end of three hours, when the operation was finished, it was ascertained to have risen to 68°. The quantity of butter was twenty-seven pounds, of a quality much the same as that produced in the third experiment, but decidedly inferior to that of the first and second. A gallon of the churned milk weighed eight pounds eight ounces.

In the fifth experiment, fifteen gallons of cream were used as before, at the temperature of 66°, and the weight per gallon eight pounds. The churning occupied two hours and a half; at the end of which space the temperature was found to have risen to 75°, being an increase of 9°. The quantity of butter was twenty-five pounds eight ounces, of a quality sensibly inferior to that produced in any of the former experiments; being of a less promising appearance, a soft and spongy consistence, and not so pleasant to the taste. The weight of a gallon of the churned milk was eight pounds seven ounces.

Results.

From these experiments it appears that cream should not be kept at a high temperature in the process of churning. In the first experiment, where the temperature was lowest, the quantity of butter obtained was in the greatest proportion to the quantity of cream used; and as the temperature was raised, the proportional quantity of butter diminished; while in the last experiment, where the mean temperature of the cream had been raised to 70°, not only was the quantity of butter diminished, but in quality it was found to be very inferior, both with regard to taste and appearance. That the lowest possible temperature should be sought in churning, appears likewise from another result of the above experiments; namely, that the specific gravity of the churned milk was found to diminish as the temperature of the cream had increased; thus showing that at the lower temperatures, the butter which is composed of the lighter parts of the cream, is more completely collected than at the higher temperatures, in which the churned milk is of greater specific gravity. In general, it was inferred, that the most proper temperature at which to commence the operation of churning is from 50° to 55°; and that at no stage of the operation ought it to exceed 65°: while, on the contrary, if at any time the cream should be under 50° in temperature, the labour will be much increased without any proportionate advantage being obtained; and a temperature of a higher rate than 65° will be injurious as well as to the quality as to the quantity of the butter.

Butter for keeping.

Butter is usually preserved for future purposes by means of common salt. The following preparation is an excellent substitute, and imparts a richer and sweeter taste. Two parts of good sea salt, one part of loaf sugar, and one of saltpetre, are pounded and mixed together. One ounce of this mixture is incorporated with every pound of butter, which is then closed up in a proper vessel, and at the end of two or three weeks it is fit for the table. When thus prepared, it has been known to retain its sweetness several years.

Dutch butter making.

In Holland the method of making butter is to allow the milk, after it is drawn from the cow, to become completely cool before it is put into the pans or cream dishes; to prevent the cream from separating from the milk by stirring it two or three times a day with a wooden spoon, and when it is sufficiently thick to churn it for an hour. When the butter begins to form, a quantity of cold water is poured in for the purpose of separating the butter from the milk; and when the former is taken out, it is washed and kneaded till the last water comes off pure. It is said that milk managed in this way yields a larger proportion of butter than by the ordinary method practised in this Country; and that it is, at the same time, of a better quality, sweeter, firmer, and well calculated for keeping.

Cheese.

Cheese is also a very important article of Dairy manufacture; of the History and Antiquities of which we have spoken in our *Miscellaneous Division.* Much, no doubt, depends on the quality of the pasture, as well as on the season of the year at which the process is conducted; but it is proved by recent experiments that a great deal is left to the skill of the farmer, and that the raw material is capable of being converted to much higher uses than the ignorant have heretofore imagined. The very first step, the coagulation of the milk, is attended with considerable consequences, as giving a decided taste and character to cheese. It is well known that the rennet which is employed for this purpose is prepared from the stomachs of young calves, and, unless great precautions are used, it is apt to become rancid, and thereby to communicate a disagreeable flavour. The method of preserving it, in the West of England, is, when the rennet-bag is cleaned, to make a strong solution of salt with two quarts of water; to add to this solution small quantities of several spices, and to boil the whole down to three pints; then, to strain the liquor and pour it on the rennet-bag; to add a sliced lemon; and, after allowing it to settle a day or two, to strain it well, and bottle it up for use. When well-corked, it will keep a year, and gives to the cheese a pleasant aromatic flavour. A decoction of the flowers of the *Galium verum*, or cheese-rennet, a plant very common in many pastures, is sometimes used as a substitute. Muriatic acid is also employed for the same purpose; and we are told, that the pungent taste peculiar to some sorts of Dutch cheese, is occasioned by the latter ingredient, infused, perhaps, in an undue proportion.

Rennet.

Colouring matter, arnotto.

The colouring matter most commonly adopted in English dairies is *arnotto*, an article which was wont to be imported from Spain; the quantity varying according to the shade required. In Gloucestershire, an ounce is allowed for every hundred pounds of cheese. In Cheshire, the method of using it is to tie up the necessary quantity in a linen bag, and to infuse it in half a pint of hot water the night before it is used, and next morning, before the application of the rennet, to mix the coloured infusion thoroughly with the milk. In some places, a piece of the unpounded *arnotto*, dipped in milk, is rubbed on a smooth stone, and the colouring matter thus obtained, is combined with the milk in the usual way.

Gloucester cheese.

In making *Gloucester* cheese the milk is used as it is drawn from the cow; and if it be too hot in Summer a little skim-milk or water is added. After the application of the colouring-matter and the rennet, the curd is carefully broken down with the hand or a knife; and next put into a vat, and pressed for a quarter of an hour. It is then turned into a tub and again broken small, scalded with a pailful of water, lowered with one part of whey, and the whole is briskly stirred. Having stood a few minutes to allow the curd to settle, the liquor is strained off, and the curd is again collected into a vat. When this is half full, a little salt is sprinkled on and well wrought into the cheese; it is then filled up: the whole mass is turned two or three times round; the edges are pared and the middle rounded at each turning. The cheese, surrounded with a cloth, is subjected to further pressure, when the process is completed.

Imitated.

In the 1st volume of the *Quarterly Journal of Agriculture*, there is "a Receipt for making cheese, in imitation of double Gloucester." The method adopted does not differ much from that now described, and the success of the attempt, which was made in Dumfrieshire, shows that the secret, if there ever was any, is now perfectly understood from Cornwall to the Scotland Firth. The quantity of *arnotto* used by the imitator amounted to about a quarter of a pound for two hundred weight of cheese; and the salt to about eight or nine ounces. It was found that a hundred quarts of milk were required for a cheese of thirty pounds; or about three quarts to the pound.

Stilton.

The directions for making *Stilton* cheese are given in the *Agricultural Report of Leicestershire* as follows: the night's cream is put into the morning's new milk, with rennet; and when the curd is formed, it is not broken, as is done with other cheeses, but taken out whole and placed in a sieve, to drain gradually, and as it drains, a gradual pressure is continued till it becomes firm and dry. It is then placed in a wooden hoop, and afterwards kept dry on boards, and turned frequently with the cloth binders round it, which are tightened as occasion requires. When the cloths are removed, each cheese is rubbed with a brush once every day, and in damp weather twice, for two or three months. This cheese has been successfully imitated in other districts, an account of which will be found in the *Quarterly Journal*, No. VI. and in the *Prize Essays and Transactions of the Highland Society*.

Cheshire.

Cheshire cheese, which it is found more difficult to imitate than any other, is made in the following manner. The cream of the preceding evening's milk is skimmed off, and poured into a pan heated with boiling water, and a third part of the same milk is heated in the same way. The new milk of the morning and that of the preceding evening being thus prepared, are introduced into a large tub together with the cream. Then are added, first the colouring matter, and afterwards the rennet. The whey being removed, the curd is cut into slices, and repeatedly turned over and pressed with weights. It is next broken with the hand into small pieces, put into a vat, and strongly pressed, and being transferred afterwards into another vat, the process of breaking down and pressing is renewed two or three times. The last time, the vat is heated to a certain temperature, and a tin hoop or binder is put round the edge of the cheese. Six hours are spent in the processes now detailed, and eight hours more are necessary for pressing the cheese, during which time it should be twice turned in the vat. Next morning and evening, it is again turned and pressed, as well as in the morning of the third day, about the middle of which it is removed to the salting apartment, when the outside is well rubbed with salt, and a cloth binder is passed round it. During a week, while the cheese remains there, it is turned twice a day, and as it is left for some days longer to dry, it is turned once and well cleaned daily. It is then transferred to the store-room, which should be kept moderately warm, and protected from a current of air, to avoid the risk of cracking, and turned every day till it becomes perfectly dry.

Parmesan.

No cheese is more highly esteemed than *Parmesan*, which is produced on the plains of the Po, near Lodi. Its peculiar qualities, we are informed, depend more on the manner of making it than any thing else. The cows are a mixed breed, between the red Hungarian, or Swiss variety, and those reared among the Lombards. The chief peculiarity in their feeding is, that they are allowed to eat in the fields four or five hours out of the twenty-four; all the rest of the time they are stalled, and get hay. Both this pasture and hay are chiefly from irrigated lands. The cheeses are made entirely from skimmed milk; half of that which has stood sixteen or seventeen hours, and half of that which has stood only six. The milk is heated and coagulated in a cauldron, erected in a very ingenious fire-place, being an inverted semicone in brick-work, well adapted for preserving heat, and for the use of wood as fuel. Without being taken out of the cauldron, the curd is broken very small by an instrument consisting of a stick with cross-wires; it is again heated, or rather scalded, till the curd has attained a considerable degree of firmness; it is then taken out, drained, salted, and pressed, and in forty days it is fit to be put in the cheese loft. The peculiarities of this cheese seem to depend on the mode of scalding the curd; though some allege that the feeding of the cows is not without its effect. But for a more minute detail, we refer the reader to the XXIst Volume of the *Farmer's Magazine*; Cadell's *Journey in Carniola*; and Loudon's *Agriculture*.

Other cheeses

There are various other cheeses in common use, such as the *Chedder*, the *Dunlop*, the *Lincolnshire*, the *Norfolk*, the *Wiltshire*, the *Cottenham*, and the *Suffolk*; but as the process of making is nearly the same in all, we shall not repeat descriptions which would exhaust the patience without conveying any particular knowledge. We shall simply remark that cheeses ought to be kept in a dry airy place; and that the leaves of Tutsan, the *Hypericum androsæmum*, or of the Yellow Star of Bethlehem, or even the young twigs of the common Birch, are useful in preventing the depredations of mites.

Leases and Rent.

General principles.

Few subjects in Agriculture are attended with greater difficulty than the proper mode of fixing the duration of Leases and the amount of Rent. With regard to the former, it may be observed, that when they are short and clogged with a number of restrictive clauses, they are equally injurious to the proprietor and to the occupier of the land, and have therefore been justly regarded as one of the most serious obstacles to the improvement of the soil. As to rent again, no general principle can be stated which is not liable to certain objections. Some writers have suggested that one-third of the produce should be appropriated to the landlord. But as land of inferior quality requires a more expensive mode of cultivation than richer fields,—more skill, capital, and industry, to improve and keep it in a productive state,—the fourth part of the produce might be considered as the fair value of rent. Nay, from the recent examination of some very intelligent Agriculturists before a Committee of the House of Commons, even the fifth part of the actual produce of poor land was deemed an equitable return to the landlord. In all leases, therefore, founded on such principles, the quality of the soil must determine the proportion to which the proprietor is entitled in name of rent. Perhaps the main considerations connected with this subject might be examined under the following heads; namely,

Inquiries.

I. Whether it is more for the interests of Agriculture that the lands of a country should be let on lease, than that they should be occupied by tenants at will?

II What is the proper length of a lease, and what are the reasons of preferring one period to another?

III. Whether ought the rent to be a constant money-payment, or a *fixed quantity* of produce, or a fixed *proportion* of the produce of the land?

IV. Whether ought there to be any stipulations in a lease with respect to the management of the farm; and to what points ought they to be directed?

V. Whether ought a farm to be let privately or publicly. And whether ought the highest bidder, supposing him to be in other respects unobjectionable, always to be preferred?

VI. Whether ought houses and buildings to be erected by the landlord or tenant?

Leases preferable to tenancy at

I. As to the first question, whether it is more for the interests of Agriculture that land should be let on lease, or be occupied by tenants at will, it may, we presume, be determined by an appeal to the fact, which of the two has been found to call into action the greatest share of capital, industry, and skill. If guided by this principle, we shall have no difficulty in deciding in favour of leases, in preference to the system of renting land from year to year By the former method, say on a lease of nineteen years, the tenant is perfectly certain of reaping the benefit of the capital expended in improving the land; and consequently, may be expected to apply his skill to the improvement of his farm without hesitation. He can also, with perfect security to himself, adopt the most improved rotation of cropping, which, let it be observed, is generally to make a present sacrifice for a future advantage; whereas, if he is a tenant at will, in the strict sense of that phrase, he cannot be expected to do either the one or the other. Nothing would be more absurd, than for a tenant whose term of removal may be only twelve months hence, either to lay out capital, or to adopt a system of culture, the return from which could be expected only at a distant period. We are aware that many tenants at will, from the practice on the estate, or the character of the proprietor, feel a degree of security nearly approaching to that which is conferred by a lease. Though this, however, be the case in some particular instances, it cannot apply to landlords in general. A tenant, therefore, so circumstanced, cannot fail to apprehend, that were he to make any great improvement on his farm, a higher rent might be exacted.

Advantages derived from Leases.

There is one objection which we have heard stated to letting land on a lease of nineteen years, namely, that if the farm happens to be too low rented, the tenant continues during the lease, and enjoys a portion of the produce which should have fallen to the share of the landlord; but, on the other hand, should the stipulated rent prove too high, the landlord must submit to a deduction. This objection is plausible; and may, on a superficial view of the case, appear conclusive against the system of letting lands upon lease. Those who take this view, however, very probably forget, that the security of a lease for a fixed and definite period, has been one of the principal causes of the rapid progress of Agriculture during the last fifty years. If the same impulse could have been given to Agriculture in the hands of tenants at will, the view entertained by such persons would, no doubt, be correct. But this is supposing a state of things which cannot possibly exist. For it proceeds upon the idea, that Man will display the same energy, and make as great exertions for the acquisition of an object which another may enjoy, as he will for that which he knows will be exclusively his own. Indeed, there seems great reason for thinking, that had the practice of letting lands to tenants at will been universal, the rental of the Country would not have exceeded two-thirds of what it is at present; and, therefore, although a landlord may occasionally be obliged to accept of a rent somewhat lower than his lands are worth, still he is a great gainer on the whole. It may be supposed, that we have overrated the effect of leases, but, when it is taken into account, that previously to their introduction almost every improvement was effected by the proprietor, and that in all districts in which they are generally adopted, the tenants have relieved the landlords of this burden, the benefit resulting from this method will not be questioned. Of course we are here speaking of such improvements as add to the productiveness of the soil, and at the same time yield a profit on the capital expended. In short, it may be held, that no tenant at will, possessing an ordinary portion of common sense and prudence, can be expected to lay out capital, which will not be returned within a very short period; and this, it is obvious, amounts to laying out no capital at all on that description of improvements which make the largest return.

Disadvantages of tenancy at will.

By the conditions of letting, he might be bound to a certain mode of cropping, which would in some measure tend to prevent the deterioration of the lands; but every operation would be performed in a slovenly manner, and with a view as far as possible to save expense. If, on the other hand, from the character of the landlord, or practice on the estate, the tenants were perfectly secure of not being removed from their farms, it is equally obvious in this case, that the cultivation of the lands would not be carried to the highest pitch; because most tenants would feel, that were they to improve their farms highly, a larger rent might be exacted. And this might occur even with liberally disposed landlords, as an experienced eye and very considerable skill are requisite, to discriminate betwixt that productiveness which is the result of natural fertility, and that arising from high improvement and skilful management. This is a risk, to which all tenants at will must know they are exposed; and in the majority of cases, they will avoid making improvements of which they are not certain of reaping the benefit.

II. With these few remarks, we shall proceed to notice the *second* point; namely,—"What is the proper length of a lease,—or what are the reasons for preferring one period to another?"

Advantages of Leases [illegible] neteen and one and [illegible] years.

The circumstances of farms, as to situation, soil, and improvement, are so various, that it is impossible to fix on any length of lease which ought to be preferred in every instance. Where the land is rich, and in a highly improved state, a shorter period may suffice, than in those cases in which extensive improvements must be executed by the tenant, and the means of effecting them are at a distance. On the whole, however, when we consider the immense benefits which Agriculture has derived from leases of nineteen or twenty-one years, we are disposed to think, that it would not be easy to fix on any period more advantageous for the greater part of lands which have been under cultivation. This period seems well adapted for inducing the tenant to execute promptly those improvements which are generally the most profitable, while, at the same time, it affords ample space for his reaping a full and fair return for the necessary outlay. When the period of the lease is much further extended, many tenants are apt to feel, that there is time enough to reap the benefit of an improvement, even though its execution be delayed for a few years; and consequently, their exertions at the commencement of the lease are less prompt and vigorous; the effect of which, in many instances, is to give rise to a dilatory and listless mode of proceeding, which often leads to the neglect or total abandonment of many improvements contemplated at the commencement of the lease. On the other hand, if the lease be for a period much shorter than nineteen years, the tenant, except in situations very favourably situated for manure and other means of improvement, does not feel that he has sufficient time for putting his lands in a very high state of cultivation, with a reasonable prospect of being remunerated. For it must be kept in view, that profit from superior culture is not derivable to any considerable extent, from merely bringing the lands to a high degree of fertility, and in a few years, by severe and injudicious cropping, reducing them again to their former state. Profit can only be derived to the fullest extent, by *keeping up* and *directing* the capabilities of the soil, whether natural or acquired, to the production of those crops which will prove immediately profitable to a certain extent, and still more by the influence which they exercise on the succeeding ones. This cannot take place, except in a very few cases, if the lease be much shorter than nineteen years.

Renewals.

On the whole, we have no hesitation in giving the preference to nineteen or twenty-one years, as the period most advantageous to the interests of the landlord, the tenant, and the community at large; though, as we have stated before, there may be cases where a shorter period would not be attended with any very striking disadvantages; and there are others where a considerable extension might prove highly beneficial. It would, in our opinion, be a great improvement, if the lease could be renewed at the end of the fifteenth or sixteenth year; as the tenant's exertions are necessarily lessened during the last four or five years of the lease. We would strongly recommend to landlords, when they have a proper tenant, to effect this arrangement with him. The oftener this can be done without giving the latter reason to expect it at the commencement of his lease, the better for all parties.

III. The *third* question to be considered is,—"Whether the rent ought to be a constant money-payment, or a fixed quantity of produce, or a fixed *proportion* of the produce of the farm?"

Object of rent.

This the reader is aware, involves a point of considerable difficulty; and one which has been of late the subject of much controversy and discussion. The object which most writers on the subject have had in view, is the discovery of a principle of paying rent, by which the tenant shall give the precise worth of the farm *each* year of the lease. This appears to us a state of things which never can be attained.

Disadvantages of the metayer system.

We shall, in the first place, offer a few remarks on the comparative merits of a fixed money-rent, and *a fixed proportion* of the yearly produce: and on this head we may observe, that the fluctuations which have occurred of late years in the *money-price* of farm produce, from the changes in the value of the currency, and the occurrence of harvests more or less productive, would be apt on the first statement of the question to decide us in favour of a fixed *proportion* of the produce of the farm, or the *metayer* scheme. Of this system, however, we are disposed to think very unfavourably, because its whole tendency is to check enterprise and improvement. Its practical operation is well illustrated by the state of Agriculture in those Countries where it prevails; for which see, among others, an excellent account in Chateauvieux, *Lettres Ecrites d'Italie en* 1812 *et* 1813, and the *Annales Agricoles de Roville*, published about four years ago at Paris. No tenant would expend capital when he knew that the landlord was to come in for a third, fourth, or fifth share of the additional produce resulting from its application. It is a system applicable only to Countries where the tenantry have little or no funds, and must look to the landlords for stocking their farms. Indeed, so pernicious does it appear to us, that we see no chance of the Agriculture of a Country becoming really prosperous where that system of letting lands is universal.

Doubts respecting a fixed money-rent.

From a fixed money-rent, no great inconvenience seems to have been felt in this Country, previously to the passing of the Bank Restriction Act in 1797. The depreciation of the currency, however, which necessarily followed that measure, and the great proportion of deficient harvests which occurred between 1797 and 1812, (see Tooke *on High and Low Prices*,) to which we may add the extraordinary circumstances, Political and Commercial, in which the Country was placed, occasioned such a rise in the price of corn, as produced, in the minds of some landlords, a dislike to a fixed money-rent. The same circumstances had a very different effect on the farmers. A fixed money-rent was, in their opinion, the only way in which land ought to be hired. It was, however, the combined effect of these and other circumstances, that disclosed the imperfections of this mode of paying rent; and led, in many cases, to the adoption of another, which is to be next noticed. But before doing so, we shall submit a few remarks on a point connected with this subject.

Farming capital.

Some landlords, we believe, are under the impression that they suffered greatly from their lands having been let, during the period of high prices, on leases of nineteen years, at a fixed money-rent. This, we are much disposed to think, is a mistaken view. It ought to be recollected, that about the middle of the last century, the amount of farming capital was extremely small. It had, no doubt, been gradually accumulating from the period of the Revolution, about which time improving leases greatly increased between 1780 and 1812.

Consequent increase of rent.

were, in a few instances, introduced; but even at the close of the XVIIIth Century, it was very far from being adequate to the improvement and cultivation of the Country. It was during the period from 1780 to 1812, but especially during the latter half, that the farming capital, in the Northern parts of the Kingdom especially, received an accession which made it nearly equal to the proper cultivation of the land. And this accumulation of capital, let it be observed, arose chiefly from the tenantry holding leases for a period of years at a fixed money-rent. During that period of Agricultural prosperity, the Art was prosecuted with a degree of spirit and enterprise unexampled in this, or perhaps in any other Country. As a natural consequence, it attracted a great number of individuals from other professions, which, with the increased capital in the hands of the tenantry in general, produced an immense competition for farms, and ultimately raised rents to the highest pitch the lands were worth, even if the average prices of the fourteen years preceding 1812 had continued. During that period of excitement, the landlords, as the leases expired, reaped a considerable share of the advantage in the rise of rent obtained, and, perhaps, still more from the improvements effected by the tenantry on their estates. But they are deriving, and will continue to derive, a still greater benefit from the increase of farming capital and skill, which those years of prosperity called forth. The progress then made in the knowledge of the Art, and the additional capital acquired, have, beyond all doubt, enabled the tenantry to pay during the last ten or twelve years, at least from fifteen to twenty per cent. more rent, than they could have done from 1750 to 1800, supposing the prices of farm-produce to have been the same at both periods. In this way, there is reason to think, that the landlords are more than remunerated for any sacrifice they made during the high prices; and there can be little doubt, that Agriculture has, at the same time, been essentially and permanently benefited.

Advantages of a fixed money-rent

From what has been said it is obvious, that a fixed money-rent, though it does not appear to have been attended with any loss to the landlords, has proved highly beneficial to the interests of Agriculture; still it must be admitted, that the late alteration in the value of the currency, and the changes which have been made on the corn laws, have had the effect of putting the capital of those tenants paying a fixed money-rent, in the power of the landlords; and though in most instances, we believe, the proprietors were too liberal-minded to avail themselves of the advantage thus obtained over their leaseholders, it is a state of things, against the recurrence of which, a provision, as far as possible, should be made.

Greater advantages of a fixed quantity of produce.

On the whole, though a fixed money rent appears much preferable to a *fixed proportion of the produce*, there seems great reason to think, that a fixed *quantity* of produce convertible at the average prices of each year, is less objectionable than either of the modes noticed; and upon this we shall offer a very few remarks.

A fixed quantity of produce has the important advantage of providing fully and completely against variations in the price of corn, arising either from changes in Commercial policy, or in the value of the currency; and at the same time has *no effect whatever* in damping the exertions of the tenant, as he knows every bushel he can produce beyond the landlord's share is entirely his own. These are advantages of great value even in a National point of view, inasmuch as they secure the landlord, in the first place, in obtaining the value of his lands *during* the lease; and secondly, go far to prevent any great destruction of farming capital. This mode does not, indeed, provide for the difference of price arising from more or less favourable harvests. This, however, can be remedied, to a certain extent, by fixing a maximum and minimum price—the former, to guard the interests of the tenant, in years of extraordinary scarcity—the latter, to protect the landlord from the lowness of prices arising from unusual abundance. Great judgment, however, is required in fixing the maximum in elevated and exposed situations, as an error in this particular might lead to the ruin of an industrious tenant in unfavourable seasons. With these checks judiciously applied, though the rent in any one year may not be precisely what it ought to be, still the disparity betwixt it and the prices, will not in any case be such as to depress the tenant, to the extent of either checking his enterprise, or diminishing his means for the profitable cultivation of his farm. Neither will the interests of the landlord at any time suffer materially. Indeed, a fixed quantity of produce convertible at the average market prices, seems to us to protect the interests of both parties, as far perhaps as is practicable. The same principle, in our opinion, might be beneficially adopted in fixing the rent of pasture-lands, provided the same means were taken to authenticate the prices of cattle, sheep, wool, and dairy-produce in each County, as is taken for ascertaining the prices of corn. This subject is deserving of serious consideration, and the plan, with little difficulty, might be carried into effect. We shall only say in conclusion, that the view here taken, has been borne out by many years' experience, in several parts of the Country, in which that mode of fixing the rent of corn lands has been in operation.

IV. The *fourth* inquiry is,—"Whether ought there to be any stipulations in a lease, with respect to the management of the farm; and if there should be stipulations, what ought they to be?"

Necessity of restrictive clauses in leases.

Although the stipulations in leases must of necessity vary according to the circumstances of each particular case, we do not think they can in any one instance be dispensed with. In those districts of the Country in which the principles of Agriculture are little understood, restrictive clauses are, during the whole lease, indispensable: *first*, to protect the interest of the landlord; and *secondly*, in some degree to lead the tenant to a better system of husbandry. There is little chance, however, of a tenant of skill and capital adopting an injurious course of management, during the first half of a nineteen years' lease; but in the latter half, the interests of landlord and tenant begin to diverge, and in the last year or two, become nearly opposed to each other:—it being then the interest of the landlord to have the lands in the highest possible state of cultivation, so as he may obtain the greatest rent they are worth upon the renewal of the lease; while the interest of the tenant is obviously to extract from the soil all he can before his right of possession is at an end. A judicious person, in framing a lease, will keep this in view, and endeavour to construct the clauses as to management, so as to protect the just rights of both parties. And we are satisfied, that restrictive clauses at the end of a lease will be least objected to by those of the tenantry who have the clearest view of their own interest; for such persons know that a deteriorating system of cropping cannot be pursued far, with advantage to themselves. Besides, when this practice is general, the loss sustained during the first four or five years of the new lease, is much greater than any paltry profits obtained by improper cropping, in the latter years of the old one. Indeed, the practice cannot be too strongly reprobated; because, instead of benefiting any party, it is extremely prejudicial to all, and not least to the tenants themselves. It would be easy to establish this beyond all question, but it would lead to details which might neither be interesting nor useful in a general treatise.

Objects of restrictions

The principal object, then, of all clauses in leases, ought to be, to put it in the power of the tenant to manage and cultivate his farm upon the most approved principles known at the time of his taking possession, and to allow him to avail himself of any improvements which may take place in Agriculture, or otherwise, during the currency of the lease; and on the other hand, to give security to the proprietor, that his lands will be properly cultivated during the whole period, but especially during the last five or six years. It is, as formerly stated, impossible to say what the clauses of a lease ought to be in any particular case, without a knowledge of the whole circumstances connected with the farm; and it is equally impossible to frame any conditions which would be generally applicable. All that can be done, is to state the principle upon which such restrictive clauses should be inserted.

Their nature.

In every case, a landlord must, either of himself, or by the advice of those in whom he can confide, determine the proportion of exhausting crops which his land can profitably carry,—keeping in view the nature of the soil, climate, situation, and other circumstances,—and must frame the restrictive clauses so as to prevent that proportion from being exceeded, and to provide for a due quantity of putrescent manure being regularly applied. Although many objections might be stated to binding a tenant to crop and cultivate his land according to a specific plan, even during the latter years of the lease, we are of opinion, that any departure from good culture for four or five years out of nineteen or twenty-one, is so detrimental to the interests of all parties, that it ought by all means to be prevented. And, perhaps, no better general principle could be applied, than that the tenant should not be allowed to depart from the system he has pursued during the previous years of the lease.

Object in letting.

V. With these observations, we shall next advert to the *fifth* query, namely, "Whether ought a farm to be let *publicly* or *privately*? and whether ought the highest bidder, supposing him to be in other respects unobjectionable, always to be preferred?"

The object which ought to be kept in view in letting lands, is, to obtain their fair value from tenants of respectability, who are possessed of adequate skill and capital for the proper management of their farms. That mode of letting them, therefore, ought to be adopted, which affords the best chance of attaining these objects. To us, the chance of accomplishing the end in view seems much greater by private than public letting. By the former, the proprietor can exercise a more deliberate judgment in regard to the merits of the candidates, and the tenant in regard to the value of the farm.

Advantages of private letting.

A higher rent may no doubt be obtained at an auction, but this is no good reason in favour of such a method, as there are few things more detrimental to Agriculture than over-rented farms. Tenants so situated, seldom make exertions, or display a spirit of enterprise, consistent with their own interest, or the interest of their profession. As farms are, in our opinion, much more likely to be over-rented, and to fall into the hands of an inferior description of persons, by being let by auction, than by receiving private offers, we would, on that account, prefer the latter mode. At a public auction, there is a degree of excitement which sometimes leads a bidder to go further than his judgment in his cooler moments would dictate; besides, some are apt to offer, trusting to the knowledge of the preceding bidder rather than to their own.

As to whether the highest bidder ought always to be preferred, we are decidedly of opinion, that capital, intelligence, and skill, ought, in most cases, to have a preference; and there can be no doubt, that the landlord who is guided by this rule, will, in general, consult his own interest, and the interest of Agriculture.

VI. As to the last point, namely, "Whether houses and buildings ought to be erected by the landlord or tenant? and if by the latter, how should he be indemnified for them?"

Buildings ought to be erected by landlord.

It appears to us, that the buildings and houses ought, in general, to be erected by the landlord. The sum necessary for this purpose, is more than the tenant can be expected to possess beyond what is required for the stocking and improvement of the farm. Besides, such erections can be made by the landlord at as little expense as by the tenant; and consequently, when executed by the former, the effective agricultural capital of the Country is greatly increased. It is worth observing, perhaps, that the landlord, having a permanent interest in the property, will take care to erect buildings, both as to stability and extent, suitable to the general uses of the farm: whereas, it can scarcely be expected, that a tenant, having only a temporary interest, will be guided by the same views.

Bad effects of the metayer system on the Continent.

We might have expanded the considerations under the third head to a much greater extent, and taken a review of the *metayer* system, as it operates in many parts of the Continent, in which the farmers pay a fixed proportion of their produce to the landlord in name of rent. This has been pronounced by Mr. Arthur Young "the most detestable of all modes of letting land," in which, after running the hazard of many heavy losses, "the defrauded landlord receives a contemptible rent; the farmer is in the lowest state of poverty; the land is miserably cultivated; and the Nation suffers as severely as the farmers themselves." Notwithstanding the numerous changes introduced by the Revolution, this objectionable scheme prevails in more than the one half of France, and throughout the greater part of Italy. We need not add that Agriculture has made no progress in either Country, in the midst of numerous improvements derived by all other pursuits from the general cultivation of the Physical Sciences.

COMMERCE.

Definition of Commerce.

COMMERCE is the interchange of commodities, whether manufactures or agricultural products, for money or for other commodities: in the latter case it is called *Barter*. Some persons consider that all buying and selling carried on among ourselves ought to be called *Trade*, and that the name of Commerce should be appropriated to our foreign transactions; but this distinction seems hardly justified, either by the etymology of the respective words, or by the practice of merchants, with whom "foreign trade" is as frequent, or rather a more frequent expression than "foreign Commerce."

We propose for the principal subjects of the present Essay,

1. A Historical sketch of Commerce; and
2. Its condition in the present Age, as well in England as on the Continents of Europe and America.
3. Connected with these, will be a series of observations on collateral subjects; such as money, or the circulating medium of Commerce; the mines of gold and silver, particularly in America; and the use of Bank paper during the last hundred years.

Origin of Commerce.

The advantage of an interchange of commodities, of one person supplying what was needed by another, must have been obvious in the earliest stages of Society. Such interchange, however, must have been on a very insignificant scale among Tribes living in the state of hunters, and seeking their subsistence, not from domesticated animals, but from the chase and the precarious spoils of the forest. Such appears from Scripture to have been the state of the central part of Asia, in the Ages following the Flood; in the time of Nimrod and other predecessors of Abraham. It was the condition also of the aboriginal Greeks before Cadmus and other foreigners, arriving from the East, accustomed the natives to useful Arts; and it was the state of the chief part of England on the first invasion of the Romans. Such at the present day is the case of the Indians of North America, who roam over the vast tracts to the West and North-West of the Mississippi, obtaining by the chase quantities of furs to exchange with English and American traders, but living in other respects in great penury, and having very few commodities to barter among each other.

The state of Pasturage.

In the next stage in the progress of Society, the state of Pasturage with little tillage, the interchange of commodities is still on a very limited scale. Referring again to the Book of *Genesis*, we find this to have been the state of Chaldæa and of part of Syria in the Age of Abraham, about four centuries after the Flood, or nineteen centuries before the Christian Era. Population, although increasing, was still very thinly spread, and property became considerable in the hands of only a few, the bulk of the community being, as expressed in Scripture, "bondmen and bondmaids;" in other words, servants and labourers paid not by wages, but by maintenance. The Northern part of Arabia must have been very thinly peopled in the time of Jacob, yet his flocks, like those of his brother Esau, increased, "so that they could not dwell together: the land could not bear them because of their cattle." The consequence was that Esau removed his family, his cattle, and all his substance to a distance, and dwelt on Mount Seir. Similar to this was the state of Scythia in ancient times; and such, down to the present day, is the condition of the vast regions of Tartary. In this stage of Society families are almost always removing in quest of new pastures; there are hardly any towns, and but few villages; each household is consequently obliged to supply its own wants, whether in provisions or clothing; and the exchange of commodities is trifling, as it always must be until, tillage being introduced, population becomes stationary, and, in some degree, concentrated.

The Agricultural state;

We next arrive at the Agricultural state; the time when individuals and families drew together in hamlets, villages, and, eventually, in towns. Employment then becomes divided; persons follow separate trades; and the products or workmanship of one are exchanged for those of another. Intercourse is then carried to such a length as to be entitled to the name of Commerce. If it be asked in what part of the World was the exchange of commodities first carried to any considerable extent? we answer in Mesopotamia, Egypt, and the more fertile Provinces of the North of Arabia. For this we have the direct authority of Scripture, as well as the indirect but powerful evidence afforded by the local advantages of certain tracts of Country, such as those adjacent to the Euphrates and the Nile. In warm climates the great desideratum in cultivation is a supply of water; and population first becomes dense in districts which possess such a supply in abundance, whether from rivers periodically overflowing their banks, from streams descending from high grounds, or from a soil yielding water in wells at a slight depth from the surface. Now Civilization and Commercial intercourse depend on, or rather arise from, density of population. It is to this we should ascribe the early improvement of Egypt, which even in the Age of Abraham, and still more in that of his grandson Jacob, had become so far a cultivated Country, as to be able to afford a supply of corn to its neighbours when scarcity unfortunately prevailed among them. To a similar cause, we mean the dense population in Chaldæa, consequent on the overflowing of the Euphrates, and the ease with which the level tracts adjoining to that river were laid under water, we are to attribute the grandeur of Babylon and the power of the Assyrian Empire.

Countries in which Commerce first became considerable.

Commodities conveyed by land-carriage.

Almost all trade in those remote Ages was carried on by land, and as there were neither roads for wheel-carriages, nor bridges over rivers, merchandise was transported on the backs of camels and other beasts of burden. Traders proceeded generally in companies, for the sake of mutual aid and protection, exactly as is practised in the present day, and on a larger scale, by Caravans. It was to a company of Ishmaelites, (Arabs,) carrying spices from Gilead to Egypt on camels, that Joseph was sold by his brethren, about seventeen centuries before the Christian Era. The practice of conveying merchandise on the backs of animals still prevails in Countries in which an Englishman would expect that roads might long since have been made and wheel-carriages introduced. It is general not only in the thinly peopled Provinces of Brazil, Peru, Buenos Ayres, and Columbia, but in Mexico, the least backward part of Spanish America. That healthy and fertile region, now possessed by Europeans during three centuries, can, even at present, boast of no more than three or four highways fit to be traversed by wheel-carriages; and all the goods transported through its territory, whether manufactures imported, or produce sent down to the coast for export, are conveyed on the backs of mules and horses, a distance of several hundred miles.

Intercourse by water.

The earliest attempts to convey commodities by water were made on rivers or inlets of the sea, by means of canoes and rafts. Between these, the simple contrivances of a rude Age, and the bark fitted to proceed to the open sea and to encounter the winds and waves, the difference is very great. Ship-building and Navigation are complicated Arts, requiring both mechanical dexterity and a stock of knowledge which can exist only in a society considerably improved. Hence Commercial intercourse by sea is long in beginning, and for a time is carried on on a very limited scale. With the nations of antiquity this slowness was unavoidable, unacquainted as they were with the use of the mariner's compass, and limited in their knowledge of Geography. It was the custom of their seamen to keep within sight of land, and on the occurrence of stormy weather, not to stand out to sea, but to seek shelter in a bay or inlet. This practice, so contrary to that of modern navigators, arose from two causes; the smallness of their vessels, which were often without decks, and the habit of propelling them as much by oars as by sails. By rowing towards a bay or the mouth of a river, they were almost sure of entering it, whatever might be the direction of the wind; and the shallow draught of their barks admitted of their being run ashore beyond the reach of the tempest. Summer was the only fit season for such awkward mariners: to have gone to sea in the Winter months would have been accounted a great imprudence.

Navigation of the Red Sea

Thebes in Egypt.

One of the earliest branches of Navigation was that carried on along the Red Sea, for the transport of commodities from Arabia to Cosseir, or the port, whatever it was, which served as an entrepot for the trade of the Red Sea with Thebes in Upper Egypt. The merchandise landed at Cosseir is commonly considered to have been the produce of India, imported, in the first instance, into certain seaports of Arabia, near the mouth of the Red Sea. But whether the products were Indian or Arabian, the traffic appears to have been considerable, and to have been one cause of the great population and extent of Thebes; an extent proved equally by the descriptions of ancient writers, and the magnitude of the still remaining ruins. The other causes of the prosperity of Thebes were that the fertilizing effects of the overflowing of the Nile were turned to account in its vicinity at an early Age. The breadth of cultivated ground in Upper Egypt appears to have been greater in those days than at present, the flying sands from Libya having, in the course of so many centuries, covered a part of the Valley of the Nile, particularly to the West of the river. Thebes was centrally situated in regard to the Northern and Southern divisions of that long and fertile valley; the Nile being easily navigated, connected them, so that this city was both the residence of the Government, and a station for the deposit and exchange of the commodities of the upper and lower divisions of the Kingdom. Subsequently, the seat of Government was transferred lower down the Nile to Memphis, (nearly on the site of Cairo,) in consequence, probably, of the augmented population of the Delta, and perhaps of the advantage of comparative vicinity to the North of Arabia, Phœnicia, and Syria, Countries which then constituted so large a portion of the civilized World.

The Phœnicians.

But the foreign Commerce of the Egyptians was at no time considerable. Their Religion discountenanced Navigation, and their Government restricted their intercourse with foreigners, somewhat in the manner in which that of the Chinese acts with regard to Europeans. The Phœnicians, on the other hand, were altogether Commercial in their habits as in their laws. Sidon, the first seaport of consequence mentioned in History, was distant only one hundred and fifty miles from the mouths of the Nile, and the foreign trade of Egypt was carried on by Phœnician mariners, first of Sidon, afterwards of Tyre. The Phœnician coast abounded with timber for ship-building, and its position was central for intercourse with such parts of the World as were then advancing in civilization. Confined at first to the adjacent Countries, *viz.* Egypt, Cyprus, Cilicia, the Phœnician navigators ventured in the course of time to take a wider range, visiting and planting colonies in Crete, Greece, Libya, and Sicily. In all these Countries the inhabitants were uncivilized, and were indebted to the Phœnicians for the rudiments of knowledge and the introduction of the useful Arts. These Countries were situated to the West: but there was also a regular traffic between Phœnicia and the Southern part of Arabia, carried on partly by land, partly by water; by land from Phœnicia to Elath, a port in the Northern or upper part of the Red Sea; and the remainder of the distance by shipping navigating that sea.

Judæa, in the reigns of David and Solomon.

The next Country entitled to notice in a Commercial sense is Judæa. The Jews progressively increased in number during the long period (seven centuries) which elapsed between their settling in Egypt and the era of their greatest prosperity, the reigns of David and Solomon. In those reigns they made the conquest of Idumæa, a Province extending along the North-Eastern shore of the Red Sea, and seeing the wealth possessed by their Phœnician neighbours, they became desirous of engaging in foreign Commerce. This desire was facilitated by the friendly understanding which so long subsisted between the rulers of Tyre and David and Solomon. The latter sent yearly to Tyre quantities of corn and oil, the produce of Judæa, receiving in return foreign merchandise and a balance of gold and silver. The Jews being unaccustomed to Navigation, manned their merchant-vessels on the Red Sea by Phœnicians. The distant seaports with which they traded (Ophir and Tarshish) have not been recognised with certainty by modern Geographers, but the harbours Elath and Ezion geber, in which they landed their merchandise on returning, were situated in Idumæa. The foreign Commerce of the Jews, however, was of short duration, and seems to have been discontinued after the dismemberment of the Kingdom, which followed the reign of Solomon. Their trade in the Red Sea fell, doubtless, into the hands of the Phœnicians.

Commerce of Greece.

Greece indebted to Phœnicia and Egypt.

From Phœnicia and Egypt, Civilization and Commerce made their way to a quarter destined to become a copious fountain of instruction to the rest of the World. The easy access to Greece from the comparatively improved

Countries in the South and East, was a most fortunate circumstance. While the early annals of so many nations are replete with traditions of war and rapine, those of Greece bear testimony to the useful Arts introduced into their Country by foreigners, who became the founders of cities, the instructors of the rude inhabitants, the patrons of Agriculture and Navigation. These occurrences appear to have taken place for the most part about ten or eleven centuries before the Christian Era, a time at which Egypt had been for Ages in the enjoyment of a regular Government, and the seat of a considerable population. The improvements thus introduced into Greece, and the gradual increase of her towns, of Argos, Mycenæ, Athens, Thebes, Sparta, Elis, Corinth, brought the Country into the state in which it is so clearly described by Homer; who, whatever may be thought of his embellishments and exaggerations in some respects, is entitled to our full confidence when describing the limits of the respective territories, the state of Society, and the degree of Civilization existing in his time. To the accuracy of his Geographical descriptions an ample testimony is borne by the writer of all others the best qualified to judge, we mean Strabo.

Extent of her colonies.

The Age of Homer is generally placed about eight centuries before the Christian Era. The progress of improvement in Greece was afterwards checked by intestine troubles. The Dorians, a rude Tribe from the North, invaded the Peloponnesus, and succeeded in expelling from it the descendants of Pelops, the Princes of the second or third generation after those who are described by Homer as governing the chief part of the Peninsula. This invasion is called in History the Return of the Heraclidæ, and is considered to have taken place about eighty years after the war of Troy. The expatriation which followed was termed the Eolic migration, the exiles taking their course Northward in the direction of Thrace and Phrygia. In Athens the line of succession being altered in consequence of political events, the sons of the last King led a colony to the opposite coast of Asia Minor, where Ephesus and a number of other towns soon rose to importance; this was called the Ionic migration. Rhodes, eventually so important as a place of trade, was one of the earliest colonies of the Greeks; Cyrene, on the North coast of Africa, was another, while the almost equally remote island of Cyprus was settled partly by Phœnicians, partly by Greeks. But the principal foreign settlements of the Greeks were to the West, in Italy and Sicily. In Italy they founded successively Cuma, Rhegium, Tarentum, Thurium, Brundusium; in short, nearly half the maritime towns in the South. In Sicily they founded Syracuse, Agrigentum, Catania, Messina, Leontini, and a number of other towns, all on or near the coast, so as to keep up a Commercial intercourse with the Mother Country. Of these various migrations the earlier were compulsory, arising from political dissensions at home; but when the advantage of a change of residence became duly appreciated, succeeding removals took place voluntarily, and for the purpose of improving (as in the emigrations now making to our North American colonies) the circumstances of individuals. The motives and inducements were similar in either case: the territory of the parent States in Greece was limited; population was progressively increasing; and land, as in modern Europe, was high-priced, while in the colonies it was granted to settlers on very easy terms. Hence the rapid increase and eventual prosperity of several of the Grecian colonies; of Sybaris, Crotona, Tarentum, but in particular of Syracuse, which attained a degree of population and wealth beyond that of any city in Greece, not even excepting Athens.

In Asia Minor.

In Italy.

In Sicily.

The coast of Greece, number of inlets.

No Country is better situated than Greece for carrying on intercourse by Navigation. Its coast is of great length, and indented in many parts by the sea. A reference to the Map shows no less than ten extensive inlets similar to that of the Gulf of Corinth, each provided with one or more good harbours. Hence an early acquaintance with Navigation, if that name can with propriety be used in the case of barks without decks, propelled in general by oars, unprovided with anchors, and having only one mast which was raised or taken down according to circumstances. Such was the Greek marine in the time of Homer, and during the three centuries which elapsed between the Age of that Poet and the national improvements which preceded the invasion of Greece by the Persians.

Her inland territory.

The inland territory of Greece, mountainous and unprovided with roads, was not favourable to Commercial intercourse, or to the progress of National improvement as far as it depends on the union of several States into one. It was, however, highly favourable to the good government of small communities. Each town had its adjoining plain which supplied provisions and other requisites: the compact position of the population enabled them speedily to unite and cooperate if their freedom was threatened by a neighbouring State, or by an ambitious citizen at home. There was in those petty Republics, no distant Province supplying either a tribute or a military force which might be directed against the rights of the citizens. The public revenue proceeded wholly from the latter, and the military establishment being composed entirely of them, all had a similar interest in resisting an infraction of the Constitution. Hence arose the independence of the different States of Greece during several centuries, and an advance in Commerce and productive industry generally, greater than would have taken place under an absolute Government.

Her trade limited.

Still the Navigation and Commerce of Greece were very limited even in her most prosperous time: they took place chiefly between the Mother Country and the colonies planted in Italy and Sicily to the West; in Ionia in the East, and in Thrace in the North. The more distant voyages of Grecian traders were, in a Southern direction, to Egypt; in a Northern to Trebizond on the Euxine, and to the coasts of the Adriatic. In a Western direction they hardly ever ventured beyond Sicily, leaving the maritime intercourse with Spain, Sardinia, and the South of Gaul to navigators of a bolder character, the Carthaginians.

Alexandria in Egypt.

The extensive conquests of Alexander the Great gave rise to new arrangements in regard to the trade of Greece with Egypt and India. The obstinate resistance made to his arms by Tyre impressed him strongly with the resources of a maritime State, and as he ascribed the chief part of the wealth and power of Tyre to its trade with India, it was natural that, after destroying that city, he should seek to establish a naval station in a position adapted for carrying on both that and other branches of Commerce. Such a position he soon discovered near the Western mouth of the Nile, where Alexandria, founded by him, became, and continued for many centuries, the chief Commercial city in the East of the Mediterranean, and after the ruin of Carthage, in the World. Its situation was well adapted for the intercourse of Egypt with Greece, Italy, and other Countries; the Nile bringing to it the various products of the interior, and affording, on the other hand, a capacious inlet for imports. In regard to the trade with Arabia and India, Alexandria possessed, still more than Tyre, the advantage of a ready access to the Red Sea.

Of Carthage.

Carthage: magnitude of her trade.

Such was the Commerce of Greece in different Ages: at no time, it must be admitted, was it of so much importance as might have been expected from her extent of coast and advanced Civilization. Carthage, on the other hand, was altogether Commercial. Founded by a colony from Tyre, she soon equalled and eventually far surpassed the parent State. The sphere of Carthaginian Commerce was in the West of the Mediterranean; in Mauritania, Spain, the South of Gaul and Sardinia; likewise in Sicily and Libya. It extended also beyond the Straits of Gibraltar, in one direction to the coast of Morocco, in another to Portugal; or, as is often asserted, to the Western coast of France and the English Channel, where tin was a great object of attraction to the merchants. Tradition states that Carthaginian expeditions, equipped at the public expense, carried their discoveries greatly beyond these limits; to the Baltic in the North and to the remotest part of Africa in the South. But all that is known with certainty is that such voyages were attempted by order of Government; that Hanno was commander of the Southern, Himilco of the Northern expedition. Unfortunately the records of both have perished, and in the absence of other evidence the probability is that the African squadron did not carry its discoveries beyond the Canary Islands, in the 28th degree of North latitude. If we thus circumscribe the maritime progress of the Carthaginians, we can have no hesitation in restricting our belief in respect to that of the Phœnicians; and in treating as an amusing fable their alleged circumnavigation of Africa, related to Herodotus by Egyptian Priests.

Her political power.

We shall not, however, incur the risk of exaggerating when we ascribe to Commerce the origin of that power which enabled the Carthaginians to carry on extensive wars and to inflict severe blows on the rising greatness of Rome. Fortunately for the latter, their contests did not begin until Rome had extended her dominion over nearly all Italy, and possessed, in her citizens and allies, a population capable of speedily repairing the enormous waste of life sustained in the conflicts of Trebia, Thrasymene, and Cannæ. Of the progress of the Carthaginians in the useful Arts our means of judging are extremely imperfect in consequence of the destruction of their Capital; but from the number of their settlements, and the amount of their public revenue, there is reason to think that their productive industry must have been carried to a great extent: while the proportion of eminent men in the direction of their councils and armies, affords, to a certain degree, an argument in favour of their institutions. The charges brought against the Carthaginians by Livy and other Roman writers, are to be received with considerable distrust. Had not this State been unhappily cut short in its career, had time been given to it to improve the National education, to extend and mature its Commercial undertakings, there is every reason to conclude that it would have proved a great example of the benefits arising from persevering industry, and have materially conduced to the advancement of general Civilization.

Of Rome.

The Romans averse from Navigation.

The situation of the Romans in respect to Commerce was altogether different. Their military habits, and the want of a convenient seaport for their Capital, estranged them from naval pursuits. They constructed galleys for the sole purpose of opposing the Carthaginians, and their frequent losses from tempests, consequent on the unskilfulness of their mariners, rendered them averse from augmenting their navy. In the IId Punic War, the great operations were by land: hostile armies invaded the heart of their territory, and the expeditions requiring shipping, we mean those to Spain and Sicily, were of subordinate importance. At the close of this eventful struggle the power of Carthage was so much broken, and the dominion of Rome, first over Sicily, afterwards over Greece, became so absolute, as to give her the command of whatever naval power those Countries possessed, and to make it unnecessary to augment her shipping at home. This was still more the case after the course of events had added Asia Minor, Syria, and eventually Egypt, to the Roman Empire. The whole of the coasts of the Mediterranean was now subject to one Power; no maritime district ventured to attack another; and piracy, hitherto a great annoyance to Navigation, was effectually checked.

Such happily was the state of Roman Commerce during several centuries. An extensive trade was carried on between the Capital and the Provinces, in particular with Sicily and Egypt for corn; but the Government discovered no wish to transfer to Roman citizens the management of the shipping thus employed; they left it in the hands of its subjects at Alexandria and other remote seaports, because they saw no political motive for desiring its removal. The Imperial Rulers, strong in their military means, had no apprehension of any maritime city or district presuming, by means of its shipping, to resist their decrees; and they knew it to be impossible that a State so situated should cooperate with the uncivilized Tribes on the frontiers of the Empire, such as the Germans, Dacians, or Parthians, now the only enemies of the Roman name.

Navigation extended to the North of Europe;

This era of general Peace, particularly maritime Peace, was favourable to distant voyages, so that the most cautious inquirer may now give his belief to a Commercial intercourse between the Mediterranean and the South of England, carried on partly direct, partly overland through France. Such intercourse subsisted likewise with the German Tribes at the mouths of the Elbe and Weser, and, in a slight degree, with those in the Baltic, particularly in Prussia. In a very different quarter, we mean in the Red Sea and the Indian Ocean, considerable improvements took place in Navigation, in consequence of mariners becoming acquainted with the monsoons or periodical winds of that part of the World. Taking their departure from the mouth of the Red Sea on the setting in of the Western monsoon, they no longer confined themselves to the slow, circuitous method of sailing along the shore, but stretched boldly across the Ocean to the coast of Malabar; where, receiving their cargoes, they returned with the Eastern monsoon, so as to finish their voyage from the Red Sea to India and back, within the year. The uniform direction of

and to India.

the wind supplied the want of the mariner's compass, and enabled them to reach their destined ports with little deviation. The number of vessels employed in the trade between the Red Sea and India was above one hundred; and as, in those remote Ages, Europe could supply few commodities useful to the natives of India, a yearly export of silver was required to purchase the homeward cargoes. The amount of specie thus sent from the West to the East is computed by Pliny at a sum equal to £400,000 sterling a year; a considerable amount certainly, but far below that which might be inferred from the lofty tone in which Dr. Robertson and others treat the Commerce with India.

Of the Middle Ages.

The Roman Empire invaded by the Goths and Huns.

Venice founded; its singular position.

We have now traced the History of Commerce to the period (the middle and latter part of the Vth Century) when the Northern Barbarians made their way into the Roman Empire; into Gaul, Spain, Italy, and Africa. The consequences, in a Commercial sense, were very unfortunate, suspending in each of these Countries the free intercourse so long enjoyed under a common Government. The Empire was now divided into a number of separate and unconnected States; Navigation became unsafe; the roads, made with care by the Romans, were neglected. The increase of the population of towns, the best evidence of the extension of productive industry, was suspended. Many towns were plundered; others were subjected to repeated contributions; property was unsafe under the control of rude and lawless invaders; manufacturers and artisans withdrew or rather fled with their families to places of safety. Hence the origin of Venice in a very singular position; the town being built on a collection of small islands, separated from the main land by shallow lagoons. It was thus protected from attacks by land, and, in some degree, by sea, as vessels above a certain size could approach the town only by channels, from which it was easy for the inhabitants to remove the poles or buoys which pointed out the intermediate sandbanks. The result fully justified the confidence of the founders of Venice in its means of defence; for though its wealth soon became so extensive as to offer great temptation to predatory bands, it defied their violence, and never, until the present Age, saw a hostile force within its walls.

Constantinople.

Intercourse with India by the Caspian Sea.

Constantinople, in like manner, was long preserved amidst the general invasion of the Empire. Protected by its fortifications, it continued an asylum for the property of merchants, a centre for the intercourse of the seaports in the Mediterranean and Euxine which still carried on trade. Its communication with Alexandria was maintained even after the loss of Egypt; and its traffic with Venice proved one of the main causes of the increase of that city. With India also it preserved intercourse to a certain extent, after the occupancy of Egypt by the Saracens had interrupted the usual channel of navigation by the Red Sea. The route then adopted by merchants was very circuitous: goods were transported from the coast of Malabar to the Indus; they were made to ascend that river as far as was practicable, and thence carried by land to the Oxus, down the stream of which they were conveyed to the Caspian Sea. After traversing that sea, the vessels entered the Wolga and sailed up its stream, until they reached the part adjacent to the Don: there the goods were unshipped, carried by land to the banks of the Don, and embarked in boats which proceeded to the mouth of that river in the Euxine, where vessels from Constantinople waited their arrival. So long and expensive a conveyance was suitable only to goods of which the value was great compared to their bulk; to silks, cottons, and spices, which have at all times been the principal exports from India.

By Palmyra.

Another and a much more direct route for merchandise from India, was by sea from the coast of Malabar to the Persian Gulf, and thence up the Tigris to Bagdad, or up the less rapid stream of the Euphrates to latitude 34°. There the goods were landed and conveyed across the Desert first to Palmyra and afterwards from that city to the coast of the Levant. To this trade we are inclined to ascribe the extent and wealth of Palmyra; a magnificent city raised in the midst of Deserts. The chief objection to this route was the danger to the caravans from the Arabs; and as that hazard could not be removed in such a Country and under the political circumstances that ensued, the merchants trading with India gladly embraced the earliest opportunity of resuming the former route; *viz.* from Malabar to the upper part of the Red Sea, thence by land to the Nile, and down that river to Alexandria, whence the merchandise found its way to many distant ports, in particular to Constantinople, Venice, and Pisa.

Seaports in Italy: Pisa.

Among the chief seaports in Italy during the Middle Ages, Pisa, a place of great antiquity, took a lead, so early as the Xth Century. It was built on the banks of the Arno, not at the mouth of that river, but about three leagues inland, a precaution often adopted in a rude Age, to avoid or at least to lessen the danger of attack from the sea. A rich and spacious plain surrounds the town, which is of considerable extent, its walls having a circuit of six miles. The Arno is here a full, majestic stream, dividing the town into two nearly equal parts: the quays are spacious, extending along either bank from one side of the town to the other. It had become a seaport of consequence before the Crusades, and like Venice and Genoa increased its shipping considerably at the time of those expeditions. The chief sphere of its Commerce was the Western coast of Italy, the shores of Sardinia, Corsica, and Sicily. It kept up an armed force of galleys, and held as a Commercial town a rank equal to Genoa, until the population and wealth of the latter increased in the XIIIth Century. Circumstances are now greatly altered; in the early part of the XVth Century Pisa became subject to Florence; and Leghorn, being in the immediate vicinity of the sea, has gradually absorbed the foreign trade of this part of Italy.

Genoa.

Genoa, in like manner, is a town of old date, having been a place of trade before the year 1000, and becoming, some time after, the Capital of an extensive territory; the petty States around incorporating themselves with it for the sake of protection. Acting in concurrence with Pisa, Genoa recovered Sardinia from the Moors, obtained subsequently several valuable settlements in the Levant, and had factories or mercantile establishments at Constantinople for the deposit of goods imported from Asia Minor and India. She acquired also the Island of Corsica, and in Sicily held Syracuse on account of its excellent harbour. This favourable career received, however, a check by a maritime war with Venice in the latter half of the XIVth Century which proved very injurious to both. In the next century Genoa was disquieted by party contests among her principal citizens. These were of long continuance, and had attained a great height, when, towards the beginning of the XVIth Century, Andréa Doria, so well known as a naval commander, found means to effect a reconciliation among his fellow-citizens.

Genoa is favourably situated for trade, having a harbour in the form of a half moon, above half a mile in diameter. It is enclosed by two strongly constructed moles, one on the East, the other on the West: it can admit vessels of great draught, and is protected from most of the prevailing winds. On the land side, also, Genoa has considerable means of defence, the town standing on the ascent of a hill the upper part of which is surrounded by a double wall: the outer wall is of great extent, and the inner has a circumference of no less than six miles. Viewed from the sea, the town and its environs present the form of an amphitheatre and have an appearance of great magnificence.

These Cities, together with Venice, were the chief seaports of the North of Italy during the XIth and XIIth Centuries, when the North and West of Europe sent forth so many successive expeditions to the Holy Land. The rude warriors engaged in these enterprises, accustomed to see the lower orders in the humble condition of serfs, and acquainted with hardly any buildings but a Baronial castle and its adjoining village, were struck with admiration at the regular streets, the intelligent population, and the numerous shipping of the Italian seaports.

Towns enfranchised. In Italy.

The same superiority was manifest in the North and West, on a smaller scale, in a number of the inland towns of Italy, which had by this time obtained their independence and formed themselves into communities, with a regular municipal Government. Some of the larger towns acquired their independent Constitution by Grant or Charter from the Emperors of Germany, for which they paid largely; others, at a less expense, by Grant from a neighbouring Prince; while a third class of towns, more distant from a controlling power, declined to acknowledge any superior, and assumed a Constitution of their own accord.

In the Netherlands.

Of the towns in the Netherlands, several had by this time acquired independence, and the example thus given in the two most improved Countries in Europe was soon followed in France.

In France.

There, the Sovereign reigning in the early part of the XIIth Century (Louis *le Gros*) set to his Barons an example of enfranchising all towns and considerable villages situated in the domain of the Crown.* He abolished all marks of servitude among the inhabitants of those towns and villages, empowering them by Charter (*charte de communauté*) to form themselves into Corporations to be governed by a Council and Magistrates of their own choosing. The Magistrates were invested with the right of administering justice in the town and adjoining district; of levying assessments, and of training to the use of arms the militia of the town, that they might enter on service when required by the Sovereign. The example thus given in France by the King was followed by many of the Barons, who, impoverished by the Crusades and other expensive enterprises, gladly embraced an opportunity of recruiting their finances by so easy a process as the sale of Charters to the towns within their territories. In less than two centuries the towns in France, small as they in general were, became so many free Corporations, instead of places devoid of jurisdiction, or privileges. A corresponding course was pursued about the same period in Germany, where the chief trading towns, such as Ulm, Augsburg, Nuremberg, and Frankfort, were declared "free cities of the Empire." In Spain and England immunities were granted on a similar plan to the chief towns and villages; as was done somewhat later Scotland, in those days a very backward and thinly peopled Country.

In Germany.

These Historical facts enable us to judge of the origin, progress, and eventual extinction of the Feudal System. The leaders of the uncivilized Tribes which overthrew the Roman forces, and occupied successively the different Provinces of the Empire, rewarded their followers by extensive Grants of land over which they ruled as petty Sovereigns, there being in fact hardly any other authorities Military or Civil at a distance from the Capital. The population was then almost wholly agricultural; the villages were few in number and the towns still fewer. In the course of time, particularly under Charlemagne, the population of towns and villages increased and a degree of improvement took place; so that by the XIth and XIIth Centuries a number of places had become capable of forming Corporations, and desirous of having the management of their local concerns. By the Grants or Charters already mentioned, the Prince or Baron on whom the towns were dependent, conferred the rights which they desired; which, by exempting mercantile intercourse from arbitrary imposts, gave security to property in transit, and proved highly conducive to the extension of trade.

Constantinople: its commerce and wealth.

The admiration excited in the Crusaders by the chief towns of Italy was felt in a still stronger degree at the sight of Constantinople, the only Capital which had escaped the ravages of the Barbarians. The Franks, as the natives of the West of Europe were termed in the Levant, saw there a city on a great scale, having, as they described it, "extensive walls, lofty towers, superb churches, and splendid palaces." "We could not," says a Historian of the Crusades, "have believed that there was in the world a city so beautiful and so rich." Constantinople, in the XIIth and XIIIth Centuries, was still the seat of various manufactures, and carried on a considerable trade with foreign parts; with Egypt, with India by way of Alexandria, with Venice, Pisa, and Genoa. The intercourse thus maintained between the Italian seaports and the Greek metropolis, during the Middle Ages, was one of the principal links by which a knowledge of useful Arts was preserved, and the productive industry of the Ancients connected with that of the Moderns. The Crusades had at least one good effect, that of extending national improvement and of imparting to the unlettered inhabitants of the West and North an idea of the Civilization of the South and East of Europe.

Venice: its gradual increase.

The increase of Venice was very gradual, and its ultimate greatness was the consequence, not, as is vulgarly supposed, of any single cause, such as the trade with Alexandria for India goods, but of the natural growth of population and capital in a prudently managed community. In the XIIth and XIIIth Centuries, the era of the Crusades, its power had become such as to enable it to occupy several islands and maritime districts of the Greek Empire favourably situated for trade, in particular the Ionian Islands, the Morea, and Candia. These remained long in possession of Venice, while on the main land of Italy she possessed the rich territory in which are situated Padua, Verona, and Vicenza, as well as Friuli, a fertile and extensive Country to the East, acquired about the year 1420.

---

* See History, ch. lxiii. p. 615.

Its manufactures.

The manufactures of Venice, though not extensive in any one branch, were, as a whole, great from their variety; they comprised silks, lace, jewellery, stuffs of gold and silver, mirrors, and, to a certain extent, woollens and linens. An enumeration of articles so different and so unconnected with each other, may seem strange to an English reader, accustomed to see a particular manufacture conducted on a great scale, but confined to the districts which are fitted for carrying it on by possessing local advantages, such as an abundance of fuel, an extensive communication by water, or the growth of the raw material in the vicinity. But in former times circumstances were very different; a single manufacture would not have been worth following by many persons in one town, so small was the consumption in a given district, so difficult the conveyance of any bulky articles to a distance. Hence a multiplicity of manufactures were established in one city, such as Venice, although the materials for them were not produced in its vicinity; they were brought to it from various foreign ports, and collected on one spot, an advantage which, joined to the presence of a considerable population and a consequent large supply of workmen, outweighed the cheaper living of Provincial towns, cut off, as the latter generally were, from the requisite supplies, by want of capital, bad roads, and insecure communication.

Its policy.

The form of Government in Venice was at first democratic, but assumed an aristocratic character in the XIIIth Century, after extensive trade had caused the accumulation of large property in a certain number of families. In regard to foreign States, the policy of Venice was generally pacific; yet it had to sustain, in 1508, the attack of a formidable Coalition, named the League of Cambray from the town in which the aggression was planned. Nor could Venice avoid taking a part in the repeated contests between France and Austria, for the rich territory of Lombardy; contests which were carried on with great eagerness in the reigns of the Emperor Charles V. and of Francis I. The condition of Venice at that time bore a considerable resemblance to that of Holland a century later. Pacific herself, her frontier was threatened by the struggles for the Milanese, a Country not unlike Belgium; and though feeble in native soldiers, she was strong by the power of subsidizing; for her Government raised money at very moderate interest, while powerful Sovereigns were obliged to pay a very high rate, or to desist wholly from their attempted loans.

The naval force of Venice in those days consisted in galleys, and was kept up to protect her traders against the Barbary Corsairs as well as to resist the attacks of the Turks on Candia, the Morea, and other territories in the Levant.

Its Bank; origin of the funding system.

The Bank of Venice, the earliest establishment of the kind in Europe, and which has served as a model to so many Banks in other Countries, was founded in the middle of the XIIth Century. The merchants of the North of Italy, being the first in modern Europe who became considerable in trade, were the authors of many valuable inventions and improvements, such as the use of bills of exchange, and the practice of keeping mercantile books by double entry. To these was added a system, fair in itself and beneficial so long as it was followed in moderation, but the abuse of which has entailed a heavy burden on several Countries, above all, on England—we mean the Funding system; the practice of creating and selling Government stock. Its origin was as follows. The Government of Venice having found it necessary to borrow money from the public Bank, and apprehending that it would not for many years be able to repay it, adopted the plan of making it transferable from one person to another. This arrangement was judicious, and prevented loss or complaint on the part of the creditors of the State; the value of the stock was maintained, because the credit of the Government was good, and it found a ready sale on the Exchange because the number of persons desirous to purchase stock was fully equal to those who from time to time were inclined to sell it. This practice, adopted in Italy so early as the XVth Century, was followed by the Government of Holland after the year 1600; by that of England not till 1688. These dates are useful in distinguishing the respective periods at which monied capital became abundant in each Country; for the Government of each was, we may be assured, disposed to have recourse to this tempting expedient long before, and was held back only by the limited means of their subjects.

Spain: size of her towns in the Middle Ages.

The population of Spain in the Middle Ages, though scanty on the whole, was, to a certain extent, concentrated in towns. This arrangement was necessary for mutual protection in the wars with the Moors; the open country being unsafe when hostile incursions were frequent, and a town being the only fit station for the troops, (chiefly cavalry,) which were kept either to repel an attack or to carry devastation into the Moorish territories. There are no authentic returns of the population of Spanish towns in the Middle Ages, but we can by no means agree with the writers who, like Dr. Robertson, lend credence to the traditionary reports of their magnitude. The task of rearing a family is in general so difficult that, in the absence of correct returns, we may safely take for granted that the progress of population has been slow, except under peculiarly favourable circumstances; such as those of a colony having both an ample territory to cultivate, and a connection with an old Country for a supply of settlers and the sale of its products. Such was the case of the Greek colonies in Ionia and Sicily, and such at present is the case of the United States of America. Spain had no such advantages; neither had she, like Italy in the Middle Ages, an agriculture of old date, nor, like the Netherlands, the means of easy intercourse by water. Whatever we know of the History of Spain tends to show that there, as in most Countries of Europe, population increased very slowly during the Middle Ages; and as there is very little truth in the alleged drain of her inhabitants to America, the only safe inference is that in former times, as at present, Spain was thinly peopled. Her surface is mountainous, and her agriculture often suffers from want of water; a want likely to be strongly felt in times when, from deficient machinery, irrigation was much less practised than at the present day.

The trade and manufactures of the Spaniards appear to have been confined to the supply of their own wants; their foreign intercourse was very limited. Cadiz and Madrid, now their chief cities, were in those days inconsiderable. Seville was of more importance, but whoever examines attentively the position of that town, the limited navigation of its river, or the general poverty of the times, must be satisfied that the reports of its former population and splendour were greatly exaggerated. Still more does this hold in regard to other towns, such as Tortosa, Tarragona, Saragossa, Cordova, and all of which there is reason to consider were of less importance in former Ages than at present.

The Hanse Towns.

The Association of the Hanse Towns was formed in the XIIIth Century, and subsisted above three hundred years. Its object was to provide security for mercantile property at a time when the different Governments of the North of Europe, stinted in their financial means, and seldom guided by fixed rules, afforded such security in a very limited degree. The first point with the Confederates was to repress the seizure of merchant-vessels by pirates and the robbery of goods conveyed by land; the next was to obtain justice in regard to the claims of merchants in Courts of Law. In those rude times it was the custom to consider a stranded-vessel and her cargo as lost to the owners, and as having become the property of the Baron whose lands lay along the part of the coast on which the wreck took place. It was further customary, when a merchant died at a distance from his home, for the Magistrates of the town or district in which he died, to put an arrest on his property, the removal of which became a matter of great difficulty. And if he died in a strange Country, indebted to any of the inhabitants, it was not unusual with the Police to imprison the first of his Countrymen they could find and oblige him to pay the debt.

Origin,

The town which took the lead in forming this Association was Lubeck, the trade of which had become considerable in the XIIIth Century, chiefly from its position. Situated at the South-Eastern point of the Baltic, it was the natural entrepot for the trade of Prussia, Poland, and Livonia with the North-West of Germany; in the same manner as Hamburgh, from its ready access to the North Sea, was the fit port for communicating with the Netherlands and England. The distance between these towns by land being small, (only forty miles,) frequent conferences took place in regard to their mutual interests, and the result was their concluding a Treaty in the year 1241, by which the two cities bound themselves to use their utmost efforts for the protection of trade by sea and land. Progress, Brunswick, the chief inland town in the North-West of Germany, and connected in trade with both Hamburgh and Lubeck, was not long in acceding to the Treaty, and, in 1252, Deputies from each of the three met at Lubeck, where, among other arrangements of importance, they took steps for establishing factories in London and Bruges, as well as in a very different quarter, Novogorod in Russia. They assumed the name of *Hanse*, from an old German word signifying a Union or Association, and being, of course, open to new members, they were joined in the course of the next century by a number of cities and towns, such as Amsterdam and other seaports in the Netherlands; Dantzic, as well for itself as for the lesser towns in the North of Poland; and Cologne for the different trading places on the Rhine. In the XVth and XVIth Centuries, when the Confederacy may be said to have attained its highest point, the League comprised no less than sixty-four commercial towns, and was capable of asserting its rights by arms, by carrying on naval operations on a large scale. Their power was repeatedly felt by their neighbours. Thus the passage of the Sound by merchantmen being under the control of the Danish Government, which tried more than once to impose an arbitrary toll or tribute on the passage, the Hanse Towns equipped a fleet on each occasion, and obliged the Danes to desist from their claims.

Such were the motives for forming and maintaining this Confederacy; we come now to the causes of its dissolution. and Decline. As Civilization diffused itself in the North of Europe, and the different Governments made a point of protecting trade, as well by sea as in their respective territories, less exertion was required on the part of the Hanse Towns. It became evident also from the example of Holland, that trade prospered most when each seaport, or each mercantile district, was left to manage its own concerns. Hence a gradual relaxation in the bonds of the Confederacy; so that during the last two centuries the name of Hanse Towns has been confined to Hamburgh, Bremen, and Lubeck.

These towns have still mercantile Consuls in London and elsewhere, but they are occupied with the concerns of their constituents only; not with those of the former members of the League.

Bruges.

Of the trading towns in the North of Europe, the most remarkable in that early period (the XIIIth and XIVth Centuries) was Bruges. In those days of imperfect Navigation, to make a voyage from the Mediterranean to the Baltic and to return before the end of Summer, exceeded the ability of the mariner; hence the advantage of an intermediate station in which vessels arriving from the South might at once land and deposit their silks, wine, and other commodities, taking on board, in return, a cargo of the more bulky but equally useful products of the North. Bruges was fixed on by the Hanse Towns for this purpose: its situation was central; the adjoining country was well cultivated and peopled; while the town, nearly twelve miles distant from the sea, was beyond the reach of piratical incursion. Bruges had no navigable river, but it was the point of junction of several canals, and the one leading to the sea was of ample breadth and depth. The extent of ground occupied by the town was great, but the population, perhaps, at no time much exceeded the present number, forty thousand, for, in consequence of unfortunate differences between the citizens and the Government of the Netherlands, much of the foreign trade of Bruges was transferred to Antwerp towards the close of the XVth Century, the time at which it was about to become greater than ever, because the mercantile intercourse of the North of Europe began then to acquire a great extension.

Antwerp.

The large vessels which were now coming into use, and which required considerable depth of water, gave an additional value to so fine a port as Antwerp. The Scheldt is there much broader and deeper than the Thames at London, and there are ample means of inland communication both by that and other rivers. The XVIth Century was the time at which these advantages were turned most effectually to account. English merchants fixed their staple at Antwerp instead of Bruges; vessels repaired thither from the South as from the North of Europe; the city walls were successively enlarged so as to contain the increasing population; and the trade of London being then only in an incipient state, Antwerp was, as regarded foreign intercourse, the most busy seaport in the North of Europe. Unfortunately her fair prospects were marred by political dissensions; by the arbitrary conduct of the Spanish Government under Philip II., and by the war that ensued, leading in 1585 to the memorable siege and capture of the city. Many of the merchants then removed to Amsterdam, and directed thither their consignments of goods. And in the following century, when the war was suspended, and all was tranquil in the Netherlands, the Dutch having the command of both sides of the Scheldt, effectually prevented the revival of the trade of Antwerp.

Hamburgh.

Hamburgh, more fortunate than either of the above towns, has in general escaped an interruption of its trade. It was founded at an early date, and was originally little more than a fortress; but the advantage of its position brought it trade and population, as the Civilization of the neighbouring Countries advanced. Subject for a time to the Counts of Holstein, it gradually obtained an extension of its privileges, became virtually independent, and continued so after that Province was incorporated with the Kingdom of Denmark. In the extent of its water communication Hamburgh may be compared to a Dutch seaport. An arm of the Elbe forms there two harbours, one on the East for boats, another on the West for ships. Another river, the Alster, forms beside the town a large bäsin resembling a lake, and within the town another of less extent, which serves as a harbour. Though Hamburgh is nearly eighty miles distant from the sea, the communication is easy on account of the great breadth of the Elbe. The same cause facilitates the access from Hamburgh to the interior of Germany for several hundred miles. The effect of these various advantages was to render Hamburgh in the Middle Ages a port of considerable consequence, though by no means to be compared to what it afterwards became. Vessels from the South of Europe proceeded to Hamburgh as soon as the improvement of Navigation made it unnecessary for them to shorten their voyage, by stopping at Bruges, as did ships from the Baltic, after the route by the Sound was generally adopted for the export of Baltic produce. Lubeck remained, like Bruges, comparatively stationary, after the XVth Century; because the chief utility of both was as intermediate ports, and the increased dexterity of mariners after that time enabled even distant seaports to open a direct intercourse with each other.

The Netherlands

No part of Europe has a stronger claim on the attention of mercantile men than the Netherlands, in particular the maritime Provinces of Flanders, Holland, and Zealand. In tracing the progress of Civilization, we have seen that the early improvement of Greece, that wonder of ancient times, was owing, in a great measure, to intercourse with more advanced Countries, and to the introduction of the useful Arts from Phœnicia and Egypt. The revival of trade, manufactures, and general improvement in modern Italy, the next great feature in Statistical History, is to be ascribed to various causes; to the continued intercourse of Italy with Constantinople and the remaining portions of the Greek Empire; to the natural fertility and consequent population of Lombardy; to the degree of Civilization preserved throughout the Dark Ages, in a Country so long the centre of the Roman power, and so superior both in number of inhabitants and general cultivation to France and Spain, which were merely Provinces of the Empire. But the Netherlands had none of these advantages: they had at no time been the seat of empire; their Government was not better than that of the other Northern nations; and surrounded by Countries which, in the Middle Ages, were very imperfectly cultivated and thinly peopled, they could derive no instruction from their neighbours. Yet the Netherlands took as remarkable a lead in national improvement, when compared with the adjacent Countries, with England, Denmark, France, and Germany, as did Italy when compared with the rest of the South of Europe. The origin of this superiority is to be sought in Physical causes; first, in the ease with which a level surface and an alluvial soil may be cultivated: and next in the means of transporting bulky goods along canals, or such great rivers as the Scheldt, the Maese, and the Rhine.

Their early cultivation.

First as to cultivation. Of the ease with which a level surface and an alluvial soil may be cultivated, we have a variety of examples, both in ancient and modern History. It is thus that we can account for the productiveness of Egypt, of the part of the Venetian territory adjacent to the mouths of the Po and the Adige, as well as of many level tracts in very distant parts of the World, as in Bengal along the banks of the Ganges, in Guiana on those of the Essequebo, the Demerary, or the Surinam. Without quitting our own Country, we may find many examples of easy cultivation and abundant produce in the fens of Cambridgeshire and Lincolnshire, which have been reclaimed by drainage during the present Age. Flanders being a Country of similar description, we need go no further to account for its early fertility and the density of its population; the latter was remarkable, first in the open country and in villages, afterwards in towns, at the head of which were Bruges, Ghent, and Antwerp.

Their navigable rivers and canals.

The next advantage of Flanders and Holland was the ease with which all bulky commodities, such as corn, wood, coals, and turf, could be conveyed from one part to another. In most Countries of Europe there are considerable distances between the mouths of great rivers: the Humber is remote from the Thames; the Elbe from the Weser; the Charente from the Garonne. But in the Netherlands these great inlets are both numerous and comparatively near to each other; they consist of the different embouchures of the Scheldt, the Maese, and the Rhine, each opening into a distinct part of the Country. Next, as to canals. In a soil both level and devoid of rocky substances, it was easy to excavate canals, and the consequence was, that the advantage of such communications was enjoyed in the Netherlands so long as four or five centuries ago, a time at which canals were unknown in almost every part of Europe, except Lombardy, and when neither France, England, nor Germany could boast of carriage roads. In those Countries commodities could be conveyed in no other manner than on the backs of mules and horses; and each district was, in a degree, confined to its local résources, at a time at which Flanders and Holland had easy means of transporting the most bulky articles.

Of these Provinces, the lead in agriculture was taken by Flanders, the soil of Holland being in those times, as at present, too damp for tillage, and being, in consequence, laid out chiefly in pasture. Manufactures were established at an early date in the towns of both Provinces, particularly in those of Flanders. But in Navigation a decided priority belonged to Holland and Zealand, admirably adapted as both Provinces are for ready access to the sea. Hence extensive fisheries, first on their own coasts, afterwards at a distance in the North Sea; hence also a coasting-trade extending, even in an early Age, to Hamburgh in the North and to Picardy and Normandy in the West. As the seamen gradually became more skilful, their voyages were prolonged on the one hand to the Baltic, on the other to Portugal and the Mediterranean. The Dutch thus became in the course of time the naval carriers of the North of Europe; other nations abstaining in a great measure from that which, with their deficient means and ignorance of seamanship, would have been a hazardous and even perilous employment. It is a curious fact, that two centuries ago, Wentworth, Earl of Strafford, when appointed Lord Lieutenant of Ireland, and anxious to proceed from Wales to Dublin, was obliged to wait until a ship of war from the Thames came round to convey him and his suite across the Irish Channel. There were in those days no Government packets, and no English merchant-ships suitable for such a purpose; the trade between England and Ireland being carried on almost wholly in Dutch vessels.

Chief Ports.

The chief seaports in the Netherlands in those times, as at present, were Amsterdam, situated near a great inland water called the Zuyder Zee; Dordt and Rotterdam, situated near the mouths of the Rhine and Maese; Antwerp, Middelburgh, Flushing, on the banks of or near the mouth of the Scheldt. Ghent is an inland town, and like Bruges, did not adjoin any great river or maritime inlet, but it communicated with the sea by a wide canal. Dordt is considered one of the most ancient seaports in Holland, and has been noted during many centuries for its trade in timber, sent down the Rhine in floats, and applied in Holland to a variety of purposes, to the building of ships and boats, as well as to the work of carpenters, joiners, and other mechanics. The timber of the growth of Holland is not large; hence it receives vast importations from Norway and the Baltic, as well as from the forests adjoining the Rhine. Rotterdam owed its increase to the facilities for intercourse afforded by the Maese, the Leck, and the maritime inlets to the South; but it was greatly surpassed by Amsterdam, which became to the North of Europe what Carthage in one Age, and Venice in another, had been to the Countries of the Mediterranean.

Rise of Amsterdam.

Without adjoining any great river, Amsterdam had access to the Rhine by a canal, and by the Zuyder Zee, to almost every part of the Country bordered by that extensive water. In early Ages, when vessels were small, and seamen were averse from long voyages, a ready access to an inland sea was of importance, and rendered Amsterdam the most commodious port in Holland for shipping from the Ems, the Wéser, and the Elbe, as well as from the coast of Jutland. The disadvantage of shallow water in the approach to the harbour of Amsterdam, is felt only by large vessels: it was of little importance in an Age when merchandise was conveyed in vessels or rather barks of light draught. Hence the early and progressive increase of this city, notwithstanding its occasional insalubrity, and the great expense of building on ground where, from the insecurity of the foundation, the houses must be erected on piles. Amsterdam was a place of importance so early as the XIIIth Century, having been one of the first seaports to join Lubeck and Hamburgh as a Hanse Town; it continued to increase during the XIVth, XVth, and XVIth Centuries, and had become the most eligible place of settlement for the merchants of Antwerp, when the capture of that city in 1585, and the oppressive conduct of the Spanish Government, led so many Flemings to forsake their homes. The following century (the XVIIth) was the prosperous era of Dutch trade, and a very great proportion of it, whether with the Baltic, the Mediterranean, or the East Indies, centered in Amsterdam.

It does not appear that the early prosperity of the Netherlands was owing to their form of Government or Civil institutions. Flanders, Holland, and East Friesland were for many Ages governed by Counts or Earls, having, like other nations of German origin, a kind of Parliament under the name of States. These three Provinces had during the Middle Ages little political connection, and were occasionally in hostility with each other. In the XVth Century, however, an end was put to such collisions, each Province becoming, by the intermarriage of the ruling families, subject to the House of Burgundy. Maximilian of Austria having married the heiress of that House, acquired her rich possessions, which afterwards passed to the Emperor Charles V. That Prince, born in the Netherlands, had naturally a predilection for his Country, and passed various edicts to advance Commerce and consolidate the union of the Provinces. He did not, however, discover much respect for their political privileges, or much solicitude to lighten the burdens brought on them by his incessant wars. A similar conduct, pursued with less judgment by his gloomy and bigoted son, Philip II., produced these paration of the Dutch Provinces, and a contest between them and Spain during more than half a century.

Hired troops and military supplies in the Middle Ages.

Italians.

Before concluding our notice of the Middle Ages, it seems fit to explain in what manner the inhabitants of places so pacific in their policy as the Commercial towns of Italy, became connected with warlike Sovereigns, and rendered themselves auxiliary to their enterprises. We read in History, particularly at the battle of Cressy in 1346, of Genoese archers, by whom we are to understand not natives of Genoa, or troops in the service of the Republic, but military mercenaries levied in the adjoining Country, in consequence of a compact or Treaty with the French or other foreign Governments. Kings had in those days no standing armies, and to form disciplined troops from among the peasantry of their dominions was a tedious and difficult task: but in a city containing such a number of artisans as Genoa, arms were readily supplied, and combatants soon came forward where there were capitalists able and willing to contract for their services. Italy was in fact remarkable in the Middle Ages for her bands of *Condottieri*, or hired troops. A similar explanation is applicable to the Flemings or Wallobns, so often mentioned among military levies in the Middle Ages. Flanders, without being more warlike than the neighbouring Countries, was the only part in the North of Europe which at that time had either a brisk traffic or a dense population. It had accordingly the means of supplying not only arms, but men far more dexterous in their use than the rustic followers of a Feudal master, whose time of service seldom exceeded forty days; for there was hardly a battalion of soldiers on permanent duty in any Kingdom in Europe before the year 1500.

Flemings.

Swiss.

The Swiss formed the third class of hired combatants in the times of which we speak, but their services were given under circumstances very different from the Italians and Flemings. Their mountainous territory could boast of neither Commerce nor large towns; their population was spread over the open country, and, in consequence of their poverty, discharged the obligation, which every citizen owed to the State, not by paying taxes, but by performing militia service. Hence there were in Swisserland many more men trained to arms than were required for the national defence; and hence also arose a readiness in the Governments of the different Cantons to transfer to foreign Governments the services of their Countrymen on certain terms, which it was usual to embody in a Treaty, or, as it was technically styled, a capitulation.

Overland traffic from Italy to Germany.

It remains that we give an example of the rude mode of conveying merchandise by land in the XIIIth and XIVth Centuries. The trade of Venice with the Levant became considerable about the time at which Augsburg, Ulm, Nuremberg, and other towns in the interior of Germany were increasing their population and traffic. The result was a considerable intercourse between Italy and Germany by land, which was carried on across the Alps, chiefly by Trent and Inspruck, through a Country too mountainous and rugged for carriage-roads, and in which, consequently, the merchandise was conveyed on the backs of mules and horses. This mode of transport was expensive, even in those days of low wages and cheap provisions, because the weight borne by these animals on their backs, being hardly a fifth part of that which they can draw on a carriage-road, many hundreds of them were required to convey the cargo of a small vessel. It is a similar want of carriage-roads which at present narrows the intercourse with Mexico and other parts of Spanish America. Mules and horses are cheap in Countries possessing extensive pastures, but their power of carrying being limited to three or four hundred weight for each animal, the expense can be borne only by articles of value, such as cottons, fine woollens, or cutlery. The cost of conveyance being thus high at the time of which we are now speaking, the traffic across the Alps was confined to valuable merchandise, such as the silks, fine cottons, and the spices of India, or the jewellery of Venice. Heavy articles, such as oil and wine, were conveyed by shipping from Italy to Bruges.

The want of carriage-roads was general throughout Europe in the Middle Ages; almost all inland traffic was carried on in the manner we have mentioned by beasts of burden, proceeding along tracts which hardly deserved the name of roads, being little else than bridle-paths. The non-existence of an effective Police, and the means of concealment and escape afforded to robbers by the extent of forests, marshes, and uncultivated land, made it necessary for mercantile dealers to afford protection to each other, and to travel in parties or companies, in the manner of an Eastern Caravan. To this must be added, the difficulty in holding a mercantile correspondence, for it is not more than two centuries since the Governments of even the most improved part of Europe began their Post-office establishments. If besides these various disadvantages we consider the inefficiency of machinery, we shall find reason greatly to modify the popular notion of the general cheapness of commodities in the Middle Ages. Wages were low; and country produce, such as corn, wool, and cattle, were to be had for little money; but the finer manufactures, or whatever required a combination of capital and skill, were in reality dearer than at present: they cost, it is true, a very small sum when purchased with silver, but a great deal when exchanged for labour or raw produce.

Such was the state of productive industry in Europe during the Middle Ages; rude, backward, and inefficient in every Country except Italy and the Netherlands. But we are now about to enter on a brighter era; on the discoveries and improvements which, slowly as they operated, had, in the course of two centuries, the effect of producing a great extension of navigation: the result of which was the discovery of America, and an import from that part of the World of the precious metals, attended with a remarkable effect on the Commerce and state of Society in Europe.

Improvements in Navigation.

Discovery of the Mariner's compass.

The discovery of the Mariner's compass, or of the property of the magnetic needle, which makes it point steadily to the North, was made about the year 1302, by an inhabitant of Amalfi, a seaport in the Kingdom of Naples. This discovery relieved seafaring men from the necessity of guiding their course by uncertain marks, such as the aspect of headlands by day, or the often interrupted view of the stars by night. The use of the compass, consequently, became general, and tended materially to facilitate voyages in the established lines of mercantile intercourse, but it was long before it extended the range of Navigation. So backward were the merchants and mariners of that Age, and so slightly were they animated by the spirit of enterprise, that half a century elapsed after this discovery, ere navigators ventured into unknown latitudes, and even then they advanced at a very tardy rate. The Mediterranean had long been explored, and the Atlantic had been sailed over to a high Northerly latitude; the region now to be visited was the Western coast of Africa, and the task of doing so fell to the Spaniards and Portuguese: not that either People could boast of much progress in seamanship, but because of all the nations of Europe, they were, in point of situation, nearest to the Country in question. The Venetians and Genoese, superior as navigators, were comparatively remote from Africa. Still more so were the Dutch and Flemings. Aided by the compass, the Spaniards now ventured to proceed to the Canary Islands, about two hundred leagues from their own shores, while in Portugal a regular plan of discovery was formed with the support of Government.

Progress of Portuguese navigation.

As yet the Portuguese vessels had ventured no further South than Cape Non, on the coast of Morocco; their next effort, which in the present Age it would be ridiculous to call an effort, was to double that Cape, and to reach Cape Bojador, which was known to be about sixty leagues to the South. That being accomplished, two small vessels were some time after equipped for the purpose of doubling Cape Bojador, and proceeding further Southward: they were sailing slowly along the shore, according to the timid practice of the Age, when a squall of wind drove them out to sea, and led to the discovery of Madeira. That island, situated in the Ocean at a considerable distance from any coast, became the object of repeated voyages on the part of the Portuguese, and accustomed them by degrees to a bolder Navigation in the open sea. In the course of years they discovered the coast of Africa so far as the mouth of the Senegal and the Cape de Verd Islands, which being within fifteen degrees of the Line, was a sufficient distance to the South to prove that the Tropical regions were not, as had been vulgarly supposed, uninhabitable on account of heat. The further progress of the Portuguese, however, was very slow, there being a general impression that little Commercial advantage could be reaped from intercourse with Countries so remote, and situated in so hot a climate. At last, in the year 1484, a flotilla, fitted out for the purpose, persevered in navigating the coast of Africa, along the shores of Guinea and Congo, advancing no less than one thousand five hundred miles to the South of the Line. A few forts were then built on the coast of Guinea, and settlers were sent out to them from Portugal. The great inducement to persevere was the hope of reaching India by the South of Africa; a hope now strongly confirmed by the figure of the coast of Africa, which from the mouth of the Gambia recedes greatly in an Eastern direction, as if to point out a route to the Country so long and anxiously sought after. Another flotilla was now fitted out, which stretched boldly towards the South, four hundred leagues further than the preceding, but meeting with a succession of tempests, was obliged to return without doubling the Cape of Good Hope, which they saw, and to which, from the weather they had experienced, they at first gave the name of Cape of Tempests. This took place in 1486: several years elapsed before fitting out another expedition: at last, in 1497, Vasco di Gama succeeded in sailing round this formidable promontory, and accomplished a voyage to India, five years after Columbus had effected the discovery of the West Indies and America.

Trade with India by the Cape of Good Hope.

In India, the Portuguese found a Country of considerable population and trade; less wealthy, indeed, than had been pictured in the imagination of ardent adventurers or credulous merchants, but sufficiently so to form a basis for extensive exports to Europe. Most of these were now directed to Lisbon, the voyage round the Cape of Good Hope, difficult as it was to the navigators of those days, being much less tedious and expensive than the route by the Red Sea, Alexandria, and Venice. But America was in a very different condition from India: it was uncultivated and almost unpeopled; containing no manufactures and little raw produce in a state for use, the consequence not of deficient fertility, but of the natives being incapable of preparing it for sale, or bringing it to the coast to be shipped. Ages elapsed before the influx of settlers from Europe, and the increase of the native population rendered the exports of merchandise from America, her coffee, sugar, cotton, cochineal, or indigo, of importance to the Commerce of Europe: the chief effect produced during the century following the discoveries of Columbus, arose from a different cause; from the increased supply of gold and silver. This subject is of great importance in a mercantile sense, and has a claim to be investigated with minute attention.

Supply of Gold and Silver from America.

The Countries occupied by the Spaniards during the thirty years following the discovery of the West Indies, were St. Domingo, Cuba, Porto Rico, and other islands in no way remarkable for the supply of the precious metals. At last, in 1521, they obtained possession of Mexico, and began to bring considerable supplies of silver into Europe. The amount of these was greatly increased after 1545, by the produce of the rich mines of Potosi in Peru. It is thus about three centuries since the import of silver from America began to be sensibly felt in Europe; and it seems fit, with a view to mark the extent of the supply at different periods, to divide that time into three equal periods. To begin with the century that elapsed

From 1530 to 1630.

From the year 1530 to 1630. At first about half a million sterling of silver appears to have been added to the currency of Europe from the mines of America annually; after which the quantity increased progressively, so as to form, towards the close of the period, an addition of about two millions annually; the whole forming an augmentation of metallic currency to the extent of about one hundred millions sterling in a hundred years, or an average of a million annually. This is, in substance, conformable to the estimate of Mr. Jacob, in his valuable publication, *On the Precious Metals*, vol. ii. p. 70. 131; after making a suitable deduction for the proportion of the produce of the mines conveyed to India or used in Europe for plate, ornaments, or manufactures. We now come to the second period; to the hundred years which intervened

1630 to 1730.

From 1630 to 1730. The produce of the American mines continued to increase largely during this century, but as the export of silver to India, and its use in plate, ornaments, and manufactured articles, was far greater than before, the remainder, forming the addition to the currency of Europe, ought not to be computed at more than a million and a half, or two millions annually.

1730 to 1830.

From 1730 to 1830. The course of circumstances continued for many years the same as before: the mines increased in produce, but the export to India was maintained, and the consumption of silver in plate, watches, gilding, received a great extension; so that the yearly addition to the metallic currency of Europe appears to have been on an average nearly as in the former century; *viz.* from a million and a half to two millions annually. If this addition was so nearly uniform, how are we to account for the remarkable fluctuation in prices which has taken place in the last forty years? we mean, their continued rise until 1814, and their continued fall since that date. The answer is, that these fluctuations had little connection with the state of the American mines; they were the consequence of the alternations of War and Peace throughout Europe; and, in England, of the emission and contraction of Bank paper.

Rise in the price of commodities.

It thus appears, that during the first hundred years after 1530, the yearly addition to the metallic currency of Europe from the American mines, averaged about a million sterling a year; and in the succeeding two centuries between a million and a half and two millions sterling a year. So large an increase of the circulating currency had necessarily a great effect on the prices of commodities in Europe; but the degree of that effect has in general been loosely stated and greatly exaggerated. Since it is of great importance to ascertain as correctly as possible the extent of the rise of prices at different epochs, we shall, as before, divide the time that has elapsed since 1530 into three equal periods; beginning with the century

From 1530 to 1630.

From 1530 to 1630. According to common tradition and belief, the rise in the price of commodities in the course of these hundred years was enormous; not less than in the proportion of five to one, five hundred pounds being required in 1630 to purchase the various articles which a century before might have been bought for one hundred. And that, too, not from alteration of the coin; for such is asserted to have been the advance in prices, after making allowance for the different degradations of the coin on the part of Government during the period in question. Such is said by contemporary writers to have been the rise of prices, not only in England, but in France, Spain, Italy, and as far as there are records, in all the maritime parts of Europe; all parts, in short, which, from participating in foreign trade, were affected by the augmented supply of the precious metals. And so far as regards the price of corn, the rise appears to have been very great, whether we judge by the returns from our markets from year to year, or by the successive Acts of Parliament which regulated our corn trade during the period in question. Thus the export of wheat from England was allowed by the Act of

1562, when the home price was at	10*s*. per quarter.
1593	20*s*.
1604	26*s*. 8*d*.
1623	32*s*.
1656	40*s*.

This exhibits an advance in the remarkable proportion of four to one in the course of a century, but such evidence is to be received with great qualifications. The rise appears to have applied chiefly to our maritime districts, to the vicinity of seaports, where, on a rise of prices abroad, it was easy to buy up and effect an export of our corn. In the inland Counties there was, from the want of roads, a very limited intercourse in so bulky an article: each district supplied its own wants; corn was commonly paid for by barter or by labour; a mode of transacting which was little affected by the state of markets in the Capital and seaports. The abovementioned rise cannot, therefore, be considered to have been general either in England or on the Continent, three-fourths of which were at that time little influenced by maritime intercourse, but conducted their traffic on the primitive plan of barter. In those parts the price of corn varied much less.

Next in regard to the rate of payments for other purposes. The rise in the wages of labour during the XVIth Century, though very considerable, was by no means in proportion to the rise in the price of corn: the same distinction held in regard to manufactures, whether woollens, linen, hardware, or leather, the cost of which, in those times of deficient machinery, depended mainly on the rate of labour. These form very important deductions from the alleged rise in the proportion of five to one, and justify us in materially qualifying the assertions of an Age in which there were few Statistical returns and a considerable disposition to exaggerate. The point to be ascertained is the advance not merely in corn and other exportable produce, but in manufactures, house-rent, wages, and the other constituents of family expenditure taken collectively and computed together with the cost of provisions. Now, reckoning in this comprehensive manner, we consider that in the hundred years from 1530 to 1630, the rate of advance did not exceed two to one; that is, £200 in the latter year would have sufficed to effect the purchases or pay the services which, a century before, might have been obtained for £100.

We come now to the second century of the influx of silver from America, *viz.*

1630 to 1730.

From 1630 to 1730. During this period there was also a rise of prices, but in an inferior degree. It took place chiefly in the wages of labour and in articles of which the cost depended principally on labour. Corn did not rise either in England or in France, but there occurred in most other branches of expenditure an advance which rendered the rate of housekeeping and a provision for a family more costly by nearly a fourth than in the preceding century; so that towards the end of the period, the average rate of prices may be considered as in the proportion of five to four compared with the rate at its beginning, £250 being required in 1730 to purchase the commodities which, in 1630, might have been procured for £200.

This brings down our calculation to the last of the three periods; to the century that intervened

1730 to 1830.

From 1730 to 1830. During thirty years of this period prices were nearly stationary; after 1761 they rose progressively, but not rapidly; after 1795, and particularly after 1797, the era of the Bank restriction, they advanced in a ratio beyond all example; but after 1814 they fell with equal rapidity, so that the result of all these fluctuations is, that in the present year the price of a number of commodities taken collectively is greater than it was a hundred years ago by little more than a fifth, the cheapness of manufactures forming a counterpoise to the rise in corn and other raw produce.

The advance of prices in the XVIIIth Century appears thus to have been in nearly the same ratio as in the XVIIth.

Summary.

The result of the preceding estimate is, that a given amount of labour, provisions, raw materials, and manufactures, which might have been purchased in England

about the year 1530	for	£100 in money,
appear to have cost in 1630		200,
in 1730		250,
in 1830, or the present year		300.

It is very remarkable that the rise of prices in the first of these periods should have exceeded so much that of the second and third, although the supply of silver from the American mines continued to increase during the whole time. This is a very nice question, and a few remarks on it may tend to throw light on the state of trade and manufactures in Europe in the XVIth Century.

Rise of prices in the XVIth Century.

The effect of War and of a large Government expenditure, as has been strongly proved in the present Age, is to cause a considerable rise of prices. This effect is produced in various ways: first by the direct addition to the cost of an article from the imposition of a tax on it; next by the increase in the rate of freight and other charges on intercourse; but far more than all by withdrawing men and capital from productive to unproductive employment; from Agriculture and Manufactures to military purposes. In the XVIth Century the belligerent Powers on the Continent were Spain, France, and Germany; the scenes of their operations were Italy and the Netherlands. The rise of prices having been as great in those Countries as in England, a part of that rise is, doubtless, to be attributed to War; for this was the time at which the principal Governments of Europe increased their armies; when our Henry VIII. and Francis I. of France indulged their chivalrous projects; and when the more deliberate ambition of Charles V. and Philip II. of Spain kept the fairest portion of Europe in continued agitation. All this led to an increase of public burdens, and to an advance in the price of commodities, but not in a degree commensurate with the rise in prices which actually took place. The century that followed was still more marked by expensive Wars and augmented burdens, being the time at which the aggressions of Louis XIV. roused all Europe against France, and when the military establishments of that Country, as well as of England and Holland, were doubled and tripled; yet the rise of prices was by no means so great as in the XVIth Century. The latter must, therefore, have been increased by peculiar circumstances, the chief of which doubtless was the limited field on which the supplies of silver from America for some time acted.

The field for the use of silver was limited in this manner: the population of Europe being in those days chiefly rural, and too poor to make use of silver, that metal was current only among the inhabitants of the Capitals, the seaports, and a certain number of inland towns. Now all these places were then far below their present scale both in numbers and property. The following Table may tend to bring the question to issue, by conveying a view of almost all the towns entitled to be considered as in any degree the seats of trade and manufactures in Europe, three centuries ago.

Chief Towns in Europe in the XVIIth Century.

Italy.

Rome.

Poverty of agriculturists in the XVth and XVIth Centuries.

Such were in those days the principal cities and trading towns in Europe; the places to which the silver imported from America gradually found its way, and gave a stimulus to productive industry, to mechanics, manufacturers, navigators. Adjacent to most of these places was a considerable district cultivated in a manner less rude than the Country at large: the peasantry had there attained the rank of tenantry, and were enabled, by their intercourse with the towns, to pay their rents in money, while nine-tenths of their brethren scattered over the Provinces, were almost strangers to the use of silver, and could pay their rent no otherwise than in labour or produce.

What, it may be asked, was the collective amount of population in the various towns which we have enumerated and the neighbouring districts? It appears to have been in all between four and five millions; but to these are to be made two considerable additions: first the lesser towns, whether maritime or inland, in which there were half-yearly or yearly Fairs; and the much longer list of burghs or petty places in which there were weekly markets, and which, poor and thinly peopled as they were, have a claim to consideration in our estimate, because silver was, to a certain extent, their circulating medium. Adding the population of all these places and their surrounding districts to that of the Capitals and larger towns, we may consider the result as exhibiting the total of the European community among which silver at that time circulated. The number seems in the earlier half of the XVIth Century to have been below ten millions; while in the latter half of that period it may have amounted to between twelve and fifteen millions, among whom, and not a greater number, the silver from America appears to have been distributed.

Though the numbers we have thus assigned to the various towns of Europe and their adjacent districts are not a fourth of their present population, they will be found large when allowance is made for the total difference of the times. In the XVIth Century country work was so rudely managed, the ploughs, the tools, and implements of husbandry, from scarcity of iron, were so defective, that in every part of Europe so many as eighty persons in a hundred were necessarily resident in the country, the labour of that great proportion being indispensable to raise subsistence for the community at large. There were then, as we have shown, very few roads; and consequently few draught-carriages, for corn, wool, and other produce were conveyed on beasts of burden. Now such conveyance, being both difficult and expensive, was considerable only in the neighbourhood of towns: in country parts, that is, throughout nine-tenths of Europe, each hamlet or district was obliged to supply its wants from its local resources, scanty as they were: traffic was carried on by barter, and the only metallic currency was copper. All this shows that we must beware of judging in any degree of our farmers and peasantry of former times by those of the present Age. A better criterion will be found among the peasantry in the East of Europe, in Poland, Hungary, Russia. There, even at present, the privations are great; the mode of living extremely rude: silver is so little used in paying either wages or rents, that most of the labourers are without the means of buying woollens or manufactures of any kind; they are obliged to protect themselves from the cold of winter by a covering of sheep or lamb-skins.[*]

Improved Condition of Agriculturists.

Such in the XVIth Century was the state of the peasantry throughout Europe with the exception of certain districts in Lombardy or the Netherlands; or in the vicinity of such Capitals as London and Paris. Money-rents were very rare; they arose in process of time out of the improvements which productive industry received from various causes, above all from the increase of town population and the augmented supply of silver from America. This may be best explained by a reference to the present Age, in which we have had a very striking example of the invigorating effect of a continued rise of prices on farmers, merchants, and the productive classes generally. After 1797, that is, after our Banks were exempted from paying their notes in cash, money became abundant, and the check on the expenditure of Government was removed. Provisions, arms, clothing, shipping, were required on a scale of unprecedented amount, and all were furnished without difficulty, because the steadily continued supply of money gave a general stimulus to the productive classes. Our growth of corn being insufficient for our consumption, prices rose year after year and the circumstances of farmers improved, particularly in such parts of the Kingdom as Norfolk, Northumberland, Scotland, in which long leases are customary. Hence an increase of capital among the better class of tenants, and a beginning of capital among those who till then hardly knew what capital was. Similar to this was the course of circumstances among the tenantry of England, during the long reigns of Henry VIII., Elizabeth, and James I.: prices were in general on the rise, and our agriculturists experienced a progressive improvement of their circumstances. This improvement proceeded, it is true, very slowly compared to that of our farmers during the memorable twenty years from 1794 to 1814; but in one very material point our ancestors had the advantage; they suffered no reaction; the capital they acquired was preserved and handed down unimpaired to their sons and grandsons, prices continuing to rise during more than a century, and afterwards maintaining the advance that had taken place. For silver continued to come in, and the population of our towns, in other words the number of the consumers of country produce, was regularly on the increase.

The effect of an improvement in circumstances so long and so happily maintained, was to change the more active part of our peasantry into yeomanry; into tenants able and willing to pay their rents by money instead of by the primitive mode of labour and produce. This change, beginning with the districts adjoining the Capital and the larger towns, extended itself gradually over the more distant Counties during the XVIth and XVIIth centuries, adding largely to the national wealth, and extending the field for the circulation of silver. Holinshed, adverting in his *Chronicles* to the scanty portion of silver circulating among our farmers about the year 1500, "says, "If one of them did cast down his purse, and therein six shillings in silver, it was very likely that all the others present could not lay down so much against it." Now it is no exaggeration to assume, that in the hundred and fifty years which followed the date of this anecdote, the proportion of English farmers who paid their rents in money, and who in their buying and selling transactions made use of gold and silver, increased tenfold. A similar, though by no means an equal improvement of circumstances took place among the agriculturists in various districts of the Continent; in the vicinity of Capitals, seaports, and the larger inland towns. On the Continent there was also a regular increase in the number of the consumers of country produce, distinct from agriculturists; in mechanics, manufacturers, the professional classes, and other inhabitants of towns. In Holland this increase was rapid during the XVIIth Century; in France, Germany, Spain, and the vicinity of the Baltic, it was slow, but in steady progress. The labour of husbandmen became more efficient; their tools and implements were improved; a given number were able to raise a greater quantity of corn and other produce. The result of the whole was a surprising increase in the number of persons, whether in town or country, among whom gold and silver circulated; so that a yearly supply from America of two millions sterling was far less felt in Europe in the XVIIth and XVIIIth Centuries, than one million had been in the XVIth.

Mercantile intercourse of Europe and America.

Having now explained the rise of prices, it remains to add a few remarks on the mercantile intercourse of Europe with America in the XVIth and XVIIth Centuries. This was long on a small scale, because the thinness of the population in America restricted both the supply of produce from that Country and the demand for manufactures from Europe. The mode of conducting the trade was this. The silver sent from America to Spain was for account partly of the Spanish Government, but more for that of Spanish merchants connected with Mexico and Peru. It was landed at Seville or Cadiz, whence the portion belonging to Government was forwarded to the Treasury at Madrid, while the sums remitted for account of individuals were delivered to the merchants. On the part of the Government, these periodical supplies were distributed and expended in the purchase of arms, clothing, the pay and subsistence of troops: on the part of the merchants, in the purchase of quicksilver for extracting the silver from the ore at the mines, of clothing and tools for the mining workmen, of machinery, and of various manufactures required in Mexico and Peru, Countries in which the Art of manufacturing was almost wholly unknown. Italy and the Netherlands were the only Countries which had manufacturing towns of importance: other parts of Europe participated in the trade directly, sending to these a supply of raw materials. England, at that time too little advanced in the weaving of woollens to send abroad cloth, felt the benefit of the American trade in an augmented export of wool to the Netherlands; in the same manner as the iron mines in the North of Italy increased their supply of that material to Milan and Brescia, which were noted for their manufactures of hardware.

The Trade of Holland.

Extension in the XVIIth Century.

From the influx of silver from America, the prominent feature in our sketch of the XVIth Century, we turn to that which most strongly marked the XVIIth, the extension of the trade of Holland. No subject is more interesting and instructive than the Commercial prosperity of a Country, so limited in its extent and apparently so little favoured by Nature: in no part of the World shall we find a more striking example of the triumph of assiduity and perseverance over Physical obstacles. And first as to the causes of this prosperity. The progress of productive industry in Holland appears to have been as follows. The vicinity of so much water, as well along the coast as in the great maritime inlets, led to extensive fishing on the part of the inhabitants, first for their own supply, and next for sale to their neighbours. At the same time, the repair of the dikes and other works required to preserve so low lying a Country from the irruption of the rivers and high tides, produced habits of regular labour; while, in the third place, the practice of navigating the great rivers and the adjacent coasts, gave the Dutch a knowledge of seamanship rare in the Middle Ages in any part of Europe, except Italy. The Dutch were thus enabled to become the naval carriers, first of the North, afterwards of the South of Europe, not only conveying to a distance the products of different Countries, such as the corn, the flax, the timber of the Baltic, the wool of England, the wines of France, the oil and fruits of Spain and Portugal; but engrossing the coasting trade of most of those Kingdoms. Such was the situation of the Dutch about the year 1570, when the intolerance of Philip II. of Spain led to those Civil troubles which ended in Holland and the adjacent Provinces withdrawing from his yoke, and forming themselves into a separate State, under the name of the Seven United Provinces. From that time forward the Dutch added to their Physical advantages the still greater blessing of good Government. Having suffered greatly from Religious Persecution, and seen how much the public welfare is injured by it, they opened their Country to oppressed foreigners; and no solicitation of foreign Powers could ever prevail on them to withdraw their protection from such refugees. Toleration in Religion was accordingly complete in Holland, at a time when in other Countries it was enjoyed very imperfectly, or not at all: while in regard to the administration of justice, a strict impartiality was observed between natives and foreigners. Hence the influx into Holland of a number of valuable settlers, first from Belgium and France during the persecutions for Religion; afterwards from Germany during the Thirty Years' War; and, in some degree, from England in the Civil troubles under Charles I.

So early as the XIIIth Century Amsterdam and other Dutch seaports were of sufficient importance to be members of the Hanseatic body. Towards the year 1500 the shipping of Holland had so increased that three or four hundred sail were regularly employed in the Baltic trade, performing commonly two voyages a year each. An equal number appears to have been engaged in intercourse with France, England, and Spain. Before the year 1600 the shipping of Holland was further increased, and still more in the course of the XVIIth Century. John de Witt, who guided the affairs of his Country so long and so ably, stated in his printed Works, that in the twenty-seven years which intervened between the Peace with Spain in 1613 and the time at which he wrote, *viz.* 1670, the trade and navigation of Holland had increased one half. This period was followed by long and expensive Wars with France, involving a heavy addition to the taxation of the United Provinces, and augmenting the wages of labour in a very injurious degree. Still their institutions were so good, the advantages of the ample capital and tried industry of the inhabitants were so substantial, that their Commerce continued long to stand its ground. In the year 1700 the mercantile navy of England amounted by an official return to 261,000 tons; the seamen to 27,000. Of those of the Dutch we have no regular account, but it is probable that their numbers were fully double those of England, both in seamen and tonnage.

Causes of its prosperity.

The Government of Holland never listened to the false doctrine of endeavouring to raise or manufacture at home articles which they could obtain at a moderate price from abroad. The poverty of their soil was in some measure the cause of this judicious policy and of their extended navigation. They considered it no disadvantage to part with money to buy corn in Germany or in the Countries of the Baltic; nor did they ever stimulate a home manufacture by bounties. The trade in corn was always free, and in consequence, so long as two centuries ago, Holland was considered a depot for the occasional supply not only of England, France, and other neighbouring Countries, but of Portugal and Spain; for the warehouses of Amsterdam, according to Sir Walter Raleigh, generally contained seven hundred thousand quarters of corn, none of it of the growth of the Dutch Provinces.

If we analyze the causes of the Commercial prosperity of England, we shall find them to be partly Physical, partly Political. Among the former are our length of coast, our easy communication by water, the abundance of our coal and iron mines, and the vicinity of these mines to navigable rivers. Of our Political advantages, the chief have been the early introduction of the Reformed Religion, the check of the legislative on the executive branch of Government, and during several centuries a succession of Princes exempt, in a great measure, from a mania for War. Holland could boast neither of mines nor of a fertile soil: but in communication by water her advantages were still greater than those of England. She early enjoyed the blessing of the Reformation, and possessed in her States or deliberative Assembly, a direct though not always an effectual check on the executive branch of Government.

Decline.

Such were the causes of the extension of the trade of Holland. We come now to the reverse of the picture—to its decline. That dated from the early part of the XVIIIth Century, and had made considerable progress before 1750. Of this distressing change the

The Causes.

cause was neither deviation from sound policy on the part of Government, nor relaxed industry on that of the people, but the pressure of heavy taxation, and the insufficiency of the resources of the Country to meet its burdens; first the sums required yearly for its defence against the sea, and next the much greater payments for the interest of the debt incurred in its long-continued wars. In that respect the lot of Holland had been particularly severe. She was oppressed in the first instance by Spain, assailed in the next place by England under Cromwell and Charles II., and finally obliged to resist the unprincipled ambition of Louis XIV. during three successive Wars; efforts by far too great for so small a State.

Further causes of the decrease of Dutch navigation may be found in the improvement of other Countries, and in the measures of their respective Governments for appropriating to their own subjects first their coasting trade, and afterwards their general import and export business. Ship-building and seamanship, Arts little understood in the North of Europe during the XVth and XVIth Centuries, had now become familiar to the inhabitants of the maritime districts of England, France, Denmark, and the North of Germany. In all those Countries the Governments took steps to carry on their foreign trade by direct voyages, and to avoid the circuit of the Netherlands. Entrepots were no longer necessary when a knowledge of navigation had become general, and the quantities of produce to be conveyed were so great as to make it expedient to fetch them from the Countries of their growth.

But the trade of Holland, though reduced as regarded Europe, was still very considerable to India and the West Indies until the latter part of the XVIIIth Century, when the contests with England, partly after 1780, during our first American War, but much more after the occupation of Holland by the French in 1795, led to the most unfortunate results: to the loss of the Dutch colonies, the continued suspension of their navigation, and a great depression of their funded property. To these were added, after 1810, the anti-commercial edicts of Bonaparte, so that in the latter years of the war the Country was plunged into the greatest distress.

The return of general Peace in 1815, and the prospect of its long continuance, revived the courage of the Dutch, and led them to resume, in some degree, their Commercial activity. Without flattering themselves with a return of their former prosperity, they have good grounds to hope for a fair share of the trade of Europe. The Rhine and the Maese are now more important than ever as inlets into the neighbouring Countries, the difficulty of ascending them being greatly lessened by steam navigation; while in the maritime Provinces, the continued level of the soil is very favourable to the conveyance of bulky goods by land as well as by water. Great improvements have of late been made in the public roads, and that which in England is now sought at so heavy a charge, a smooth surface, is found in Holland almost without expense. Add to this, that the scientific discoveries of the Age promise to be beneficial to Holland, by lessening the heavy expense attendant on her peculiar position. The strength of her dikes may be increased by planting roots which in other Countries are found to give tenacity to a sandy soil; while the surprising improvements lately made in England in raising water by steam engines, cannot fail to be of service in a Country so liable to suffer from water overflowing and remaining stagnant on the surface.

Commerce of England

H[illegible]cal [illegible] trade from A.D. [illegible] to A.D. 1[illegible].

England was considerably later than Holland or Flanders in arriving at Commercial eminence. Under William the Conqueror, the Public revenue appears to have been between £100,000 and £200,000 a year, arising less from taxes than from the Royal demesnes. The population of England, which at the time of the Conquest hardly exceeded a million, increased in the course of the succeeding three centuries to somewhat more than two millions, such being the amount according to the census taken by order of Government in 1377, the last year of the reign of Edward III. The people were scattered in cottages and hamlets over the open country, or rather over those portions of it that were cultivated, for in those days marshes, forests, and heaths covered a very large extent of our territory. The villages, for they were too insignificant to be called towns, increased their population very slowly. The pastures both for sheep and large cattle were extensive: the chief export from the Kingdom was wool, and the amount sent abroad varied from £100,000 to £250,000 a year. This export took place chiefly to Flanders, and, in a small degree, to France, Spain, and Italy. London was the chief shipping port, and the English of those days being unacquainted with the Continental Languages, our foreign trade was conducted chiefly by foreigners residing in London; *viz.* Flemings, Italians, and Frenchmen. Business in bullion and coin was long carried on by Jews, but after their expulsion, in the reign of Edward I., that important branch was taken up by Italians from Venice, Pisa, and Genoa, who were all called Lombards, and who gave their name to the street so well known as the chief resort of our Bankers.

Co[illegible] [illegible]gatio

Most part of the foreign trade of England in the Middle Ages was conducted by Companies: individual capitals were scanty, and a joint stock was indispensable to repair any considerable losses arising from shipwreck or failures. The vessels employed in our foreign trade were chiefly Dutch and Italian: those in the coasting trade were English, but they were few in number; for our towns were then too small to need any great supplies of timber, coal, or other articles generally brought by water. The coal-works at Newcastle now so interesting a part of our mineral treasures were wrought on a very small scale till after the year 1300, for the fuel in common use throughout England was wood, a great part of the country being covered with forests. Coals, when first brought to London, were used (as they are at present in France) only by smiths, distillers, soap-boilers, and other manufacturers; not in dwelling-houses, the smoke being considered injurious to the health of a family. That prejudice continued during several centuries; but when it was at last removed, the superiority of coal as fuel, joined to the scarcity and high price of wood, rendered its use quite general in London, and greatly increased the shipping employed in our coasting trade.

The fisheries were carried on at an early date in the Channel, as well as on the Eastern coast, and contributed to the extension of several of our seaports, such as Plymouth, Yarmouth, Colchester, Lynn.

Effect of war on our trade.

The wars with France, waged by our Edwards and Henrys, were very injurious to our productive industry, but Civil wars are far more so than foreign contests, whatever may be the expense of the latter. In this manner the long struggles between the Houses of York and Lancaster in the XVth Century greatly checked the progress of our population, agriculture, and manufactures; keeping the nation in a great measure from reaping advantage from our extent of coast, our navigable rivers, and our mines of coal and iron. Happily, those times of strife and bloodshed were succeeded by a very long period (more than a century and a half) of domestic quiet. This repose, together with the benefit arising from the early introduction of the Reformation, and a course of government, which, though very different at different times, was, in the main, judicious, enabled the Country to recover from its misfortunes, and to establish its agriculture and trade on a solid basis.

The XVIth Century.

The reign of Henry VII. afforded almost the first example of useful laws enacted in regard to the national industry. Until then, the power of purchasing land had been confined in England, as it is at present in Hungary and other half-civilized Countries, to men of a certain rank; but a double blow was now struck at Feudal usages, for while by one Act of Parliament landholders were enabled freely to dispose of their estates by sale, by another the compulsory services of the peasantry were lessened or commuted for a money payment. Navigation, too, now began to take a wider range, and voyages were performed by English vessels to a considerable distance; to the Baltic, Spain, Portugal, and Italy. Still our intercourse with those Countries was small compared to that with Flanders and Holland, which were sufficiently advanced in Commerce to purchase our wool, hides, and other raw produce, supplying us in return with a variety of manufactured articles.

During the reign of Elizabeth the regulation of our Commerce was committed to Cecil, a prudent, impartial, and, so far as the state of information in that Age permitted, an enlightened Minister. He was very ready to grant exclusive privileges for various branches of foreign trade, such as that to the Levant, the Baltic, Africa, and, lastly, to the East Indies. Such a course, however contrary to our present impressions, was unavoidable in an Age when individuals had little capital, and when, without an assurance of ultimate advantage, they would have been neither able nor willing to incur the expense attendant on the outset of almost every mercantile settlement in a foreign Country.

We pass on to the latter part of the XVIth Century, a time at which England had enjoyed a hundred years of internal peace, and had reaped her full share of the benefit arising from the influx of the precious metals from America. Our towns were still small, and the inhabitants lived chiefly in the country, in villages and hamlets, but their situation, compared to that of their forefathers, was amended in various respects. The amount of the yearly exports and imports had increased; and so also had the personal comfort of all ranks, in food, clothing, and lodging. The dwellings of the middle and lower classes, from being little else than sheds or cabins of wood, were constructed, at least such of them as were new, of stone and brick. This was the era at which floors were substituted for the bare earth in the lower part of the dwellings, and glass became generally used in windows in lieu of the horn and lattices of ruder times.

The XVIIth and XVIIIth Centuries.

During the XVIIth Century, the Western or maritime part of Europe reaped the advantage of former discoveries, and extended its navigation both to India and America. The chief share of this Trade fell to the Dutch, whose situation might be compared to that of husbandmen practised in the labours of the field, and ready to enter on the opening harvest, as they were much more advanced in navigation and productive industry generally, than either the French or English of that Age. There was, however, a continued, though very gradual, increase of our mercantile tonnage, and a strong desire on the part of the Public to enlarge it at the expense of our Batavian rivals: hence our celebrated Navigation Laws.*

Our Navigation Laws.

So early as the reign of Henry VII. there were passed Acts of Parliament enjoining that certain commodities from abroad should be imported only in English ships, manned by English seamen. Half a century later, in the reign of Elizabeth, laws were passed to exclude foreigners from our fisheries and coasting trade; but it was in 1651, and under the influence of Cromwell, that the principal Navigation Law was enacted. Its chief dispositions were as follows.

Merchandise of the growth or manufacture of Asia, Africa, or America, to be imported only in English vessels, of which the master and chief part of the crew are English.

Merchandise of the growth or manufacture of Europe to be imported into Great Britain only in British ships or in ships belonging to the Country in which the goods were produced.

Such was the substance of the Act of 1651. In 1662 it was in some degree modified, and the injunction to import in British ships was confined to certain articles, called on that account "enumerated articles;" but these comprised all goods that were bulky, or of importance with a view to freight, such as corn, timber, hemp, flax, wine, spirits, sugar.

These laws effectually prevented the Dutch from acting the part of naval carriers between England and other Countries, and necessarily increased our mercantile tonnage, the amount of which was raised from 95,000 tons in 1660, to 190,000 tons in 1688.

Trade with North America and the West Indies.

Our North American colonies, in particular New England, Virginia, and Maryland, considerably increased their population and trade in the latter part of the XVIIth Century. The shipping then employed in our intercourse with them, though very different in size, was equal collectively to about 200 vessels of 200 tons each. There was an increase also in the trade of our West Indian Islands, the chief of which at that time were Barbadoes and Jamaica. With all these colonies our principle of intercourse was monopoly for monopoly: we required them to receive their manufactures wholly from us, and to send to England in the first instance almost all the produce they exported; while, in return, we opened to them our market of consumption, and imposed high duties on similar goods when brought to us from other parts. Thus the flax, hemp, and ship-timber imported into England from the Baltic were subject to duty, while the same articles from North America were duty free; the culture of tobacco at home was prohibited, in order that our market might be open to the tobacco of Virginia. On the other hand, we required that the rice, sugar, and other produce of our colonies destined for the Continent of Europe should be sent in the first place to England. The colonists were allowed to hold direct intercourse only with the Countries South of Cape Finisterre, *viz.* Portugal, Spain, Italy, the Levant; which not being manufacturing Countries were not likely to compete with us in the supply of finished goods.

* See that head in our *Miscellaneous Division.*

Trade with Spanish America.

Towards the latter part of the XVIIth Century, our manufactures having acquired a certain degree of extension, there took place a considerable export of them to Cadiz, for the supply of Mexico and other Spanish colonies. To this was, some time after, added an extensive contraband traffic carried on between those colonies and our West Indian Islands. The Spanish Government exacted a duty on all manufactures imported into America, and was very jealous of intercourse between their colonists and Europeans; but it was found impossible to prevent smuggling along a coast of such vast extent, and within the reach of such active navigators as the English. The occasional rencounters between our contraband traders and the *guarda-costas*, or Custom-house vessels of the Spaniards, led to repeated conflicts, and were one of the chief causes of the destructive war between the two nations, which began in 1739.

With Portugal and Brazil.

Portugal being in close alliance with England, our trade with that Country and her colonies was open and unshackled: they bought from us quantities of woollens, hardware, and other manufactures, giving us in return wine, fruit, and occasionally gold from Brazil.

With India

The nature of our East Indian trade differed materially from that to North America or the West Indies. We made no attempt to colonize India; our exports to it were less in merchandise than in silver; our returns not in produce but in calicoes, silks, and other light manufactures. Of these, the half at least was re-exported to the Continent of Europe, their consumption in England being subjected to a heavy duty, in order that we might preserve our home market for our own manufacturers.

Acts of Parliament relating to trade.

The reigns of Elizabeth, James I., and Charles I. had been the era of monopolies and exclusive grants; but under Cromwell many of these were abrogated. This was a natural result of the progress of trade: the capital, intelligence, and enterprise of merchants having increased, it became fit and even requisite to open to them the field of competition in business. Unfortunately in the next reign, (that of Charles II.,) Government lent itself to the urgency of our manufacturers and their partisans in Parliament, so far as to impose heavy duties on foreign goods. There was a general complaint on the part of the Public, that a preference was given at Court to French articles, and our Custom-house returns certainly showed an increased import of the finer woollens and linens; also of silk, paper, and glass from that Country, the total value exceeding a million annually; while the export of English articles to France was comparatively insignificant. This led, in 1678, to Acts of Parliament imposing a heavy duty on a number of commodities from France; a course followed with double vigour after the Revolution in 1688, and the ensuing war; national animosity concurring with the belief that our interests called on us to exert our utmost efforts to discourage the use of foreign articles and extend that of our own. In regard to English goods exported, Government not only returned whatever duties had been previously paid on them, but in various cases granted a bounty on the export. It forbade also the sending abroad our raw materials, such as wool or hides, and half-finished articles, such as undyed cloths, in order that all the work required to complete them might be performed in this Country.

The Mercantile system.

This was the beginning of what is called by Political Economists the Mercantile system; a system which appears in a favourable light to men accustomed to judge from first impressions, and who, conversant only with the practice of trade, have little knowledge of its general principles. Such men form their opinions on a very confined view of things; on the events passing under their eyes, without considering that these are but a few links in a complicated chain. Thus gold and silver were in their view less the representatives of wealth, than wealth itself; and they judged it highly desirable to get as much as possible of both into the Country: hence a preference to a trade, such as that with Spanish America, in which the returns were made in hard dollars. Having become possessed of a certain portion of the precious metals, the next point with the advocates of this system, was to secure our tenure; hence the repeated prohibitions against the exportation of coin. It never seems to have occurred to these reasoners that money, like any other commodity, will find its way into a Country possessing, either in produce or manufactures, articles which its neighbours are desirous to obtain; and that the true plan to bring money into a Country is to favour the increase of such commodities. Now the best method of favouring such increase is to lower duties, abolish exclusive privileges, or otherwise remove the impediments to production. That done, the Legislature may safely trust individuals with the sale of their property, satisfied that wherever there is an abundance of valuable goods, there will be no want of money to circulate them.

Another leading tenet in the Mercantile creed was that we ought to make at home whatever is required for our own consumption, even articles, such as silks, of which the raw material is not of home growth. This might be a very proper rule if every nation manufactured exclusively for itself, and if our power of selling the articles, in which we have an acknowledged superiority, such as hardware and cottons, were restricted within specific limits. But now that the World at large is open to our exports, the wisest plan evidently is to leave manufacturing industry to its natural course. One Country may excel in one branch of a manufacture, and another in another: thus as to silks, the French are superior in fancy articles, the English in several other kinds of silk; and if we can sell the latter to our neighbours, it is evidently our interest to buy fancy goods from them, rather than to maintain an unprofitable competition in making them. Let our general rule be to extend only such manufactures as are best adapted to our national means, such as require an abundant supply of fuel and an extensive communication by canals. These are hardware, cottons, woollens, earthenware, glass; and if we can supply these on better terms than any other Country, we may rest assured that their sale will be so augmented as to afford us ample means for purchasing the articles (and they are not many) which foreigners can supply on better terms than our Countrymen.

The Revolution of 1688 led to our taking a promi-

Effect on trade. The wars after 1689.

nent part in Continental Politics and carrying on wars, by means of the Funding system, on a scale of expense till then altogether unknown. This had a remarkable effect in several respects on the state of trade. First, the decided superiority of our armed shipping obliged both the French and Spaniards to trade with their colonies by means of neutrals, which proved a great advantage to Sweden, Denmark, and the seaports in the North of Germany. These Northern States benefited also by the increased demand for hemp, flax, canvass, and iron, arising out of a state of war; while from England there was an augmented export of clothing, arms, and other military stores, these forming the most convenient mode of paying subsidies to our allies. The natural effect of the war was to lessen our intercourse, at least our legitimate intercourse with France, for a great deal of smuggling continued to take place between the two Countries; *viz.* in silks and laces from France to England, and in wool and hardware from England to France.

Our inland trade.

Such was the state of our foreign trade in the middle of the last century: in regard to our home traffic we are arrived at the period when our inland communications were greatly extended; when our turnpike-roads were improved, and canals began to be excavated. Hence a remarkable increase in the manufacture of several bulky articles, such as glass, pottery, and hardware, which require canals for a double purpose: first to bring coals to the seat of manufacture during the process of preparation, and next to take the goods to market when completed.

As to corn there was not, as in the present Age, an insufficiency in our growth for our consumption; there was in general a surplus and an export of corn during the first half of the XVIIIth Century.

Interest of money.

The gradual increase of monied capital in England was indicated by the progressive though slow reduction of the rate of interest. In the middle of the XVIth Century ten per cent. a year was allowed by law, and was the usual rate for money lent on good security. In a century later, under Charles II., money was commonly lent at eight per cent; but soon after 1700 the legal rate was reduced to five per cent. Towards the middle of the XVIIIth Century the current rate on good security did not exceed four per cent.; and in Holland money could be borrowed still lower; *viz.* at three per cent.

Increase of our public burdens.

In the hundred years which elapsed between the accession of William III. and the French Revolution England sustained five foreign wars, each conducted on a great scale and at a very heavy charge. Their respective dates were:

From 1689 to 1697.
1702 to 1713.
1740 to 1748.
1756 to 1763.
1775 to 1783.

The sacrifices attendant on such wars may be reduced under two principal heads; waste of capital as shown by the yearly additions to the public debt; and loss of productive labourers, as well from the number who fall in the contest as from the still greater number who are withdrawn from agriculture, manufactures, and mechanical works to the service of Government. Confining our estimate to the former of these heads, to the increase of our public debt, we shall divide the wars during the century in question into three parts; thus,

The wars of King William and Queen Anne lasted nearly twenty years, and added to our debt...	£54,000,000
Those under George II. fifteen years	80,000,000
The American war under Geo. III. eight years............	104,000,000

Each of these contests was maintained by our Government with great ardour, and with as large a demand on our resources as it was possible to make without depreciating the currency. The waste of life and property was consequently great, but that which took place under William and Anne, was happily, in a great measure, repaired during the long Peace which followed the Treaty of Utrecht. After 1763 the season of relief did not last so long, and the magnitude of our expenditure during the ensuing war with our colonies was unprecedently large; but, on the other hand, there was by that time a great increase in our resources, in our means of augmenting our products and of recovering from the losses and burdens of war. Our canals were then in a course of extension; our towns had increased their population; the farmers were assured of ready sales for their produce at fair prices; the use of Bank paper was becoming more general; the cotton and hardware manufactures were in a state of activity; and as there was an increased demand for coal and iron, our mines for both were wrought on a larger scale. These are substantial constituents of public wealth, and they enabled our Countrymen of the last generation to recover from the gloom produced by that which at first seemed an irretrievable misfortune, the separation of the North American colonies from the Mother Country. These advantages allowed our manufacturers to meet the French and other rivals in foreign markets, and to retain the supply of the United States of America notwithstanding the antipathy of the inhabitants to England.

Next came the Commercial Treaty with France, concluded in 1786, which opened the ports of one Country to the other, and naturally led to a trial of their comparative ability to furnish the great articles of manufacture. The advantage was in most articles on the side of this Country, and the cause of it was not, as was so often contended by Bonaparte and his partisans, unfairness in the conditions of the Treaty, but the superior means of our manufacturers; a cause which still remains in full force, and deters the French Government of the present day, however friendly in its disposition to England, from renewing the open intercourse, or in other words, the competition between the two Countries.

The period from 1783 to 1793.

Our financial difficulties were great in 1783 and the following years, but our prospects gradually brightened and our trade became flourishing both at home and abroad. This improvement took place without the interference of Government, for it was assuredly not caused by bounties, prohibitions, or other artificial expedients: it was the legitimate result of our applying capital and industry to improve our national resources. Agriculture prospered although the rise in the price of corn was slight; our shipping was increased greatly notwithstanding its augmented cost. This, with the extension of our manufactures and the increase of our population, afforded a proof that, heavy as our burdens had become, we were not unable to bear them; and that the expenditure in our former wars, although occasionally lavish and often injudicious, had not, as in the case of

Holland, been carried so far as to produce a serious decline in our productive industry.

Subsequent fluctuations of trade.

The danger of such a decline was reserved for the subsequent wars, conducted as they have been with an unexampled profusion of treasure. Various causes concurred to produce this extraordinary scale of expenditure. Our Sovereign was highly popular, while the Revolutionary Government of France, and the military usurpation which followed it, excited during many years the greatest alarm. Mr. Pitt possessed the public confidence in a high degree; but above all, the abundance of money arising from the exemption of the Bank from cash payments removed the usual checks on pecuniary supplies, and rendered money abundant both with Government and the Public. Every department of productive industry felt the advantage attendant on an uninterrupted command of money. The old adage, "War begets poverty, and poverty Peace," ceased to be applicable to England, for all branches enjoyed, or seemed to enjoy, a degree of prosperity hitherto unknown in time of war. The agriculturist was enabled to pay an increased rent; the manufacturer to raise his rate of wages; the merchant found his transactions extend year after year, and professional men in very many cases doubled the incomes which they had received in Peace. No wonder, therefore, that there should be a general belief during the war that the wealth of the Country was on the increase; few persons suspected that the rise of prices and incomes was, in a great measure, nominal; and hardly any could foresee the extent of reaction at a Peace. It was not until lately, that the continued decline of prices and incomes has shown, beyond doubt, the unstable foundation of their increase during the war; and has given warning that a continued state of Peace is likely to bring our markets still lower; probably to the level of 1792.

Grounds of supposed prosperity during War.

The supposed grounds of our prosperity during the war are thus found to have been temporary and fallacious. Our manufactures increased greatly in price, but that was no indication of augmented wealth; it was owing chiefly to a rise in the cost of labour, raw materials, and other constituents of price. Since the Peace the picture has been reversed; the quantities annually manufactured have increased greatly, but the prices have fallen in a still greater ratio: the cause has been the decrease in the cost of the raw material, in the rate of wages, and in the profits of the manufacturer.

Our mercantile shipping presented a considerable increase during the war, but it was in a great measure owing to the amount of tonnage employed by the Transport Board. But of all the branches of our productive industry, our agriculture has placed in the most striking light the difference of prices in War and Peace. Corn and other country-produce continued to rise almost without interruption during the twenty years of War; they have declined with equal uniformity during the eighteen years of Peace. A similar rise and fall has taken place in professional incomes, and if, in the important head of house-rent, the decline does not extend altogether so far, it has been owing to the progressive increase of our population which since the Peace has gained thirty per cent.

This continued decline of the prices of commodities, and the consequent reduction of incomes, has come on our merchants and manufacturers in a manner as little expected, and as little understood, as was the rise of prices and increase of incomes during the War. No subject has occasioned greater differences of opinion, or a greater variety of schemes for the relief of trade. Most of these, when thoroughly investigated, are found to give but slender assurance of the benefit so fondly anticipated by their projectors: nor will merchants of reflection consider it possible that the evils arising from a lavish expenditure during twenty years, can be speedily removed by any plans, financial or commercial, however plausible. We have, however, the satisfaction of knowing that the national resources are on the increase, and that they bid fair to lessen, in the course of years, the pressure now bearing so hard on the productive classes. The first step towards a judicious application of these resources is to acquire an accurate knowledge of our situation, to obtain a distinct view of the origin and causes of our difficulties. For that purpose we shall now subjoin a summary of our Commercial and financial affairs from the entrance into office of the Statesman, from whom the extraordinary fluctuations of the last half Century certainly had their origin.

British Trade and Finances during the Administration of Mr. Pitt.

Mr. Pitt was placed at the head of the Treasury and of the Government in 1784, at the early age of twenty-five. His precocious advancement to this high station was owing to several causes; to his remarkable success as a speaker, to the veneration entertained by the nation for his father's memory, and to an impression that the eminent qualifications of Lord Chatham bade fair to reappear in his son. Our public men have often had cause to regret coming too early into office; and often have they wished undone the favourite measures of their early years. And if such was not the case with Mr. Pitt, it was owing chiefly to the Country remaining at peace during nine years after his accession to office. The course to be followed by a Minister during that period, though difficult, was not altogether so beset with perplexity as at a subsequent date. Several of our present grievances were then, in a manner, unknown. The Corn Laws were then of very limited operation; provisions were dearer here than on the Continent, but not in a degree to affect the success of our manufactures or the comfort of our mechanics. There was in those days no agricultural distress, for though the prices of corn were lower than at present, farming expenses were low in proportion, and there had been no downfal from better times; no return from Bank paper to cash payments; no complaint of having to pay in gold debts contracted in paper. The difficulties of that Age were altogether different: they arose from the discouragement attendant on the recent loss of our North American Provinces, and the low price of our public funds. Several financial reforms were required, but it was extremely unpopular to impose any new tax to meet the deficiency attendant on such reforms, or to make the revenue exceed the expenditure. The high duty on tea having led to a most extensive system of smuggling, it was very desirable to reduce the duty at least for some years, so as to cut up smuggling by the roots. A determination to that effect was taken, but it required a substantial public advantage to reconcile Parliament or the nation to the taxes granted in lieu, or, as it was called, as a commutation for the tea duty. Some of the taxes imposed at this time by Parliament, in particular the shop tax, Mr. Pitt

The duty on tea commuted.

found it necessary to abandon. In a few years, however, his difficulties were lessened by the growing produce of the revenue, consequent on continued peace, increasing population and extending trade. We possess but few statistical documents for the period in question, and the yearly increase of our numbers cannot be considered to have been so high as at present, inasmuch as vaccination was then unknown, and the cheapness of cotton-clothing, which in later years has so greatly favoured the health of the lower orders, did not then exist; but the yearly increase probably averaged one per cent. or upwards. Hence an increase in the portion of revenue arising from consumption. As to another material point, the value of our manufactures exported, it rose during the earlier years of Mr. Pitt's Ministry progressively from eleven to fourteen millions; and eventually, in 1792, to eighteen millions a year.

Commercial Treaty with France.

One of the first Commercial measures of Mr. Pitt was a Treaty with France in 1786. The speech by which he introduced this Treaty to the consideration of Parliament was replete with sound and liberal views. The conditions of the compact were fair and moderate, and in the different transactions that ensued, a balance of profit accrued to this Country, possessing, as it decidedly did, superior advantages for trade and manufactures. The Treaty thus became unpopular in France, and proved a theme of frequent declamation with Bonaparte, who, to ingratiate himself with the trading part of the French, repeatedly declared that "never would he sign such a Treaty as that which the art of the English Ministers had extorted from the weakness of the Bourbons."

The Sinking Fund.

The year 1786 was the era of another measure of Mr. Pitt, which for a long time was much vaunted—the revival of the Sinking Fund. That fund originated above a century ago with Sir Robert Walpole, in whose day our finances differed greatly from their present state; our national debt being under sixty millions, and our public revenue less than six millions a year. The long peace enjoyed by this Country under that judicious and vigilant Minister, added to the operation of even a small Sinking fund, had the effect of greatly raising the price of Stocks, so that in the year 1732 the three per cents were at 100, and in 1739 at 107. As the loans of individuals are affected in their terms by those of Government, the low interest of the public funds caused a low rate of interest generally, of which the monied men complained, alleging that they could no longer obtain a suitable return for their capital. To lessen their complaints, as well as to avoid the odium of new taxes, Sir Robert had no scruple in resorting from time to time to the Sinking Fund for the payment of various public expenses. This example his successors in office showed themselves very ready to follow; and the Sinking Fund, though at no time wholly suspended, was so often trenched on, that it did not discharge above fifteen millions of the public debt in the course of half a century.

Mr. Pitt's measure in 1786, was a revival of the Sinking Fund, nearly as introduced by Sir Robert Walpole, but with various safeguards to prevent the income constituting the fund from being diverted to any other purpose whatever. With that view the whole was put under the direction of a Commission, and the Commissioners were rendered independent not merely of the Ministry, but in some degree of Parliament. The sources of the income of the Sinking Fund were,

1. An annual million to be paid to it out of the taxes, whatever might be the state of the revenue.

2. The amount of such annuities payable by Government as from time to time lapsed or expired by the demise of the annuitants. And,

3. The interest of the Stock annually bought up by the Sinking Fund; such Stock not to be cancelled, but to be entered in the books of the Bank in the name of the Commissioners of the Sinking Fund, the dividends or interest on it going in aid of the Fund.

Such was the Sinking Fund of 1786 when brought into full operation; it extinguished annually about a million and a half of three per cent. Stock: that is, the public by paying in taxes a million sterling more than they otherwise would, paid off as much of its debt as reduced the interest by £50,000 a year. This and this only was the arithmetical operation of the measure; but benefit was expected from its principle, from Parliament giving a pledge to the world that the nation, however burdened by taxes, was determined to pay a million a year above the Government expenditure, for the purpose of lessening its debt and keeping up the public credit.

Objections to it.

It is needless to enlarge on the flattering calculations of the effect of compound interest, with which Dr. Price ushered in this boasted scheme. The annual million, as well as the other sources of income to the Sinking Fund, were evidently drawn from the pockets of the Public; in other words, they were abstracted from productive employment. The judicious Vauban, when writing on the finances of France, long since told the World, that were Governments wise, they would be sparing of taxes: he said with truth, *L'argent le mieux employé est celui qui le Roi laisse entre les mains de ses sujets.* The Sinking Fund is now little thought of: it has fallen almost into a state of non-efficiency. The question is how far circumstances, in the early part of Mr. Pitt's Ministry, were such as to justify the adoption of the measure, or to reconcile its adoption with the general admiration of his talents. Mr. Pitt was then only in his twenty-seventh year, and could not have reflected either long or profoundly on the sources of national wealth. He had read Dr. Smith's Work, and he discovered in his public speeches a very proper sense of its value; but that Work is not instructive on the subject of taxes. But the great deficiency in Mr. Pitt's elements of calculation was the absence of statistical documents, and of proofs of the tendency of this Country to prosper without any artificial aids. His natural good sense and disposition to view the future in a favourable light, might, and probably did, suggest to him reasons for considering the national prospects as encouraging; but he was ill provided with documents on which to found such an opinion with confidence. If, even at present, our public men have no adequate idea of our growing resources, it need not be matter of surprise that no man of authority in those days should have come forward to say, "Instead of making the nation pay a million a year additional, keep the taxes at the lowest possible amount, and trust to the benefit that will in a few years accrue to the Treasury from a gradual removal of the obstacles to the extension of productive industry." There were in those days no population returns; no evidence that the increase of our towns added largely to the national resources; no proper estimate of the extent of our iron mines; nor of the benefit likely to result from our abundance of coal when applied to steam machinery.

Instead of such views, Mr. Pitt was probably assailed by such suggestions as, "The price of Stocks can be raised only by continued purchases for account of Government, and these can be made only by a Sinking Fund provided with a yearly revenue; the Stockholders desire such a measure, and to the nation at large it will be an indication of vigour; a declaration that we are willing to submit to an extra burden at present in order that we may lighten the burdens of posterity." This was very plausible advice, and would be considered by the multitude as both spirited and judicious. The course of our narrative will soon show the singular measures into which Parliament was led, after Mr. Pitt's death, by the attractive name of a "system of vigour:" so that we need hardly wonder that he, young as he then was, surrounded by feeble coadjutors, and unprovided with the documents requisite to form right conclusions, should have pursued a very different course from that which he would have adopted in mature age and with more correct information.

A main cause of the Commercial and financial embarrassments of this Country, has been the unacquaintance of our public men with the principles of productive industry. Of this ignorance a striking instance was at that time given by Mr. Fox, who, though opposed to Mr. Pitt in so many of his measures, gave his cordial approbation to the Sinking Fund. This he was led to do not from a knowledge of the subject, which he never studied, but from the specious nature of the plan; perhaps from a constitutional confidence which prompted him, without much inquiry, to place a part of the burden on our own shoulders instead of those of our posterity. On the other hand Lord Grenville, so long the colleague of Mr. Pitt, and his professed admirer, subsequently altered his opinion of the Sinking Fund, and has publicly maintained that the measure was impolitic.

The French Revolution.

We are now arrived at the troubled era of the French Revolution; at the time (1792) when the Jacobins became guilty of the greatest excesses, and when the financial relief to be expected from a continuance of Peace seemed, in the view of our Court, and the major part of our Nobility, a secondary object compared to the danger that threatened us if we remained quiet spectators of the commotions in France. Till this time Mr. Pitt had maintained amicable relations with the ruling parties in France, but when they had driven their King from his throne, and declared their Government a Republic, he was called on to come to a decision on the momentous question of Peace or War. His personal wish was for Peace: both the success of his financial measures, and the prosperity of our trade, were connected with its maintenance; but after the murder of Louis, and the invasion of the Netherlands by the French, he assented, and was in a manner obliged to assent, to the alternative of War.

The determination once taken, it was conformable to his character to prosecute the War with vigour; to regard his financial savings as secondary to our military operations; and while he maintained the Sinking Fund as to form, to adopt a course which in fact suspended, and much more than suspended, its reducing powers—a yearly borrowing of money to a large amount. Our navy, and still more our army, had been on a small establishment during the preceding years, but both were increased forthwith. In the second year of the War our expenses were augmented; in the third and fourth year (1795—96) they were further increased, so that the scale of our expenditure much exceeded that of any former period.

Exemption of the Bank from paying in cash.

In raising supplies the Ministry experienced great difficulty from two causes; first the distress of trade consequent on the high rate of interest, so much of the capital of the Country being required by Government; and next the difficulty of providing for our disbursements abroad, which could not be met in Bank notes but required specie. When a loan was proposed, the anxious question in those days was not so much what was its amount, as what part of the amount would be required abroad. These were the chief causes of the adoption of that measure which distinguished the late wars from all others, and which gave Government a great and long continued, but as the result has shown, a delusive accommodation—the exemption of the Bank from Cash payments. The immediate cause of that measure was a continued drain of gold, from the Bank in February 1797; but we may safely affirm, that a step of the kind had repeatedly entered into the consideration of Mr. Pitt and the Bank Directors, as a relief from the grievances under which all parties, Government, the Bank, and the mercantile interest, laboured from the magnitude of our expenditure. Anxious as were the Bank Directors to support Government in the war, they could not, in prudence, strip the Bank of its treasure so long as they were liable to pay cash for their notes on demand. They watched, and were obliged anxiously to watch, the exchanges with the Continent, which a deficient harvest or the remittance of a large subsidy to our allies never failed to render unfavourable to us. In 1795 and 1796, both these causes had been in operation: they had impoverished the Bank as to gold, and had produced the greatest inconvenience to merchants by the difficulty of discounts. Accordingly, no sooner did the exemption from paying in cash take place, than the small notes issued by the Bank were more favourably received by the mercantile body, who hailed the change as the era of their relief, the dawn of a season of abundance. The Bank was now no longer under the necessity of watching the exchanges, or of restricting their advances to either Government or merchants, on account of their stock of cash being limited; they merely looked to the security, to the probability of the bills offered to them being regularly paid when due. The relief thus afforded to the Public was general and complete; it pervaded every part of the Country. Farmers had no longer difficulty in paying their rents, nor householders their taxes, greatly as they were now increased. The price of commodities, whether produce or manufactures, rose year after year; the same was the case with wages, salaries, professional incomes. The War was no longer unpopular, and the financial measures of Mr. Pitt were extolled as the instruments of our political salvation.

Renewal of war in 1803.

In this manner were we conducted to the end of the first war with France. Happy would it have been had we understood the precarious and unstable character of a paper currency when not convertible into cash, and had we been aware, that circumstances might, and very probably would, arise, to carry its depreciation to a serious length. During the first year of the War, renewed in 1803, Mr. Pitt was out of office, but in questions of trade and finance his opinion had at all times the greatest weight. An income-tax of five per cent. was proposed by Mr. Addington, and met with very little opposition after Mr. Pitt gave his opinion that to impose it on funded property was no breach of faith with the public creditor. On another occasion in which he dissented from a tax proposed by Mr. Addington, and adopted by a majority of the House, the members saw the Minister appear next day in his place and withdraw the Bill they had sanctioned, doubtless because he considered the dissent of Mr. Pitt as the most serious of evils. Next year, 1804, Mr. Pitt was recalled to office, but his tenure of it was unhappily too short, for in less than two years his death took place, at the early age of forty-seven, and in the midst of our contest with France.

British Trade and Finances since the Death of Mr. Pitt.

The successors of Mr. Pitt in the financial department were first Lord Henry Petty, (now Lord Lansdowne,) and afterwards Mr. Perceval. Both followed up Mr. Pitt's plan of finance, the main feature of which, after the increase of our circulating medium had relieved the wants and increased the incomes of individuals, was "to raise the chief part of the supplies within the year;" that is to borrow less than we had done previously, and to look for the chief provision for our expenditure in high temporary duties; in other words in war-taxes, so called because Government was pledged that they should continue only during the War.

When the Grenville Ministry was removed from office in March 1807, our trade and finances fell under the direction of men who moved in the footsteps of Mr. Pitt, but who, when compared to him as to information and judgment, were distant *longo intervallo*. They had not been a year in office before they discovered an unacquaintance with the course of our foreign trade, a total unconsciousness of the precarious nature of our Bank paper, by adopting a measure which Mr. Pitt would never have sanctioned—the stoppage of neutral navigation. This was effected by the Orders in Council of November 1807, a measure never thoroughly understood either by the House of Commons or the Public. These Orders were expressed in the complex style of law papers, and their true object was kept studiously out of sight, as well it might be, for never was there a Commercial edict less to be justified, or less fitted to bear investigation. The real account of it is as follows: The War had by that time lasted above twelve years, and had added heavily to the expense of our shipowners: timber, hemp, wages of seamen were all enhanced, and an extra time was generally required for the voyages of our merchantmen from the necessity of waiting for convoy. From these various disadvantages neutral vessels were free, and their navigation being carried on at less cost, they had an advantage over British shipping which could ill be brooked by the subjects of a Government which commanded the Ocean. Hence repeated attempts on the part of our merchants to cramp their navigation; attempts which had been resisted by Mr. Pitt, and which had no chance of success with Lord Grenville. But the case was very different on Mr. Perceval coming into office: from his professional habits, he was necessarily unacquainted with trade, and had unfortunately given his confidence to those lawyers and merchants who were most clamorous against neutrals. No sooner, therefore, had our attack on Copenhagen in the Autumn of 1807 succeeded, than the party in the Cabinet, whose creed was a "system of vigour," urged, and in despite, as was said, of the opposition of Lord Hawkesbury, obtained the adoption of the Orders in Council against neutral navigation. They prescribed that "neutral vessels, whithersoever bound, should put into a port either in England or in one of our dependencies, there to pay certain charges and receive a license or sanction for the continuance of their voyage." Such an edict was not, in point of form, so strong a measure as a direct stoppage of neutral navigation, but the authors of the Orders doubtless anticipated that they would have that result, particularly in the case of the Americans; as a nation claiming to be independent would hardly submit to such an acknowledgment of inferiority. The consequence was, that the American Government prevented their merchant-vessels from going to sea, and a general suspension of their navigation took place.

eutral shipping; the advantages which it enjoyed.

Stopped in November 1807.

Consequences of this stoppage.

The effects of this suspension on the trade, the credit, and the finances of this Country were pernicious in a high degree; much higher, indeed, than is even yet known to the Public, for the evil was not at once apparent; it came on us indirectly and covertly. First, as to our Bank paper, the American merchants had been highly instrumental in maintaining its credit in the following manner. They sold every year to France, Holland, and the rest of the Continent of Europe produce to a large amount; larger by three, four, or five millions than the value of the goods they took from those Countries in return. In what manner was this balance disposed of? It was paid to the Americans in money, and was sent over by them from the Continent to England, where it was applied to pay our merchants and manufacturers for the very large quantities of goods which they sent yearly to the United States. The Americans were thus the medium, or rather the cause, of *continued remittances to this Country in money or bills of exchange;* this had been the case every year since the Bank exemption in 1797, and serves to explain a fact which had surprised ourselves almost as much foreigners; *viz.* that our Bank notes should escape depreciation so long after they had ceased to be payable in cash. By stopping the navigation of the Americans we deprived ourselves of this important resource. Instead of buying our manufactures, they were obliged to manufacture for themselves, to the incalculable injury of our woollen and cotton trade; while from the Continent of Europe they could make us no more remittances because we had precluded their intercourse with Holland and the other Countries which supplied them.

Our Bank notes depreciated.

The consequence was a rapid fall in the value of our Bank notes compared to coin, at first of ten or twelve per cent., afterwards of fifteen, eventually of twenty per cent., and upwards. Other causes, it is true, cooperated to produce this unfortunate result, in particular our military expenditure on the Continent, and the large amount of specie sent abroad to buy corn; but these would have been, in a great measure, counterbalanced by remittances from the Americans had they been allowed to continue their trade. Unfortunately Mr. Perceval and several of his colleagues continued to think differently; the Americans bore their grievances in peace during four years, but at last, in June 1812, they declared war against us. In vain did Lord Liverpool repeal the obnoxious Orders almost immediately after Mr. Perceval's death: the Americans mistook his motives and persisted in the war. It lasted nearly three years, and if we make a computation of the loss of property caused to us from first to last by this unfortunate quarrel, first, by the failure of Americans who were largely indebted to our merchants; next, by the depreciation of our Bank paper; and lastly, by the war with the United States, we shall find the aggregate to be little short of two hundred millions sterling; that is, of the twenty-eight millions which we now pay annually for the interest of the public debt, no less than seven or eight millions are to be traced to our unfortunate stoppage of the trade of neutrals during the last seven years of the war!

The year 1812 was a season of trial for our finances: the war in Spain was at its height in point of expense, while Russia required all the pecuniary aid we possibly could afford her. Next year, 1813, called for still greater efforts: the chances were now in favour of our allies, and never could our resources be better applied than in their support. It became necessary to trench on the Sinking Fund: Ministers did so, but in an indirect and disguised manner. They thought it essential to have the appearance of maintaining the integrity of the Fund, and it will hardly be believed that at the time a large sum was drawn from it, there issued from Lord Bexley's office a printed paper gravely stating that the reduction of our debt would proceed more rapidly after making this abstraction, than on the former plan which abstracted nothing. So strange a misrepresentation seems almost incredible, but in truth the history of the Sinking Fund contains a series of misrepresentations quite unworthy of the Government of a great Country, and to be palliated only on the ground that, during an arduous struggle, Ministers may be permitted, for the sake of keeping up public credit, to resort to steps which in time of Peace would be altogether inexcusable. Nearly half a century has elapsed since the Sinking Fund has been held forth to the Public as our financial sheet-anchor, the instrument by which we were to be relieved from the pressure of our debt; yet the actual *bonâ fide* reduction effected by it during all that period has not exceeded thirty millions!

Part of the supplies of the Sinking Fund appropriated to the war.

It is now above twenty years since the date of our Second Population Return, which established beyond all question the progressive increase of our numbers and resources. From that time forward Ministers were relieved from the necessity of artificial expedients; fortified by such a document, it would seem that they had merely to declare to the Public that the repayment of our debt was no longer requisite, and ought not to be attempted; that the great object was to favour the extension of our productive industry, by which means our debt, though the same in numerical amount, became less in proportion to the collective funds of the nation. At times, Ministers appear to have been actuated by such views, having repealed several taxes on account of the injury they caused to trade and manufactures, such as those on salt, on coals, on hemp and silk, and the tonnage duty on shipping: but much that was injurious remained.

The occasions on which the financial knowledge of the House of Commons was chiefly put to the test were in 1811, in the discussions on the Bullion question, and in 1819 on the resumption of cash payments. What an inattention to facts did these discussions discover! how scanty a knowledge of Statistics! how great a tendency to adopt plausible theories and to hasten to premature conclusions! The causes are that the mercantile Members of the House are little in the habit of public speaking; while of the other Members, the major part are unacquainted, not merely with Commerce, but with the principles of productive industry generally. Our great Universities, at which so many of the Members have received their education, have not till very lately possessed the means of instruction on such subjects; and of the Works hitherto printed on Political Economy the chief part are obscure, intricate, abounding in theories, and deficient in practical illustrations.

Having now brought down our narrative to the close of the last War, we shall in the next place endeavour to explain,

1. The sources of our high prices and large financial supplies during that War; and
2. The causes of their diminution since the Peace.

Singular it certainly is, that in a Country in general so enlightened as this, we should still be in doubt as to a subject so nearly regarding us, and in respect to which the opinion of the Public ought long since to have been fixed. But neither our merchants nor our public men are by any means agreed about the causes of these fluctuations. The inquiry is long and complicated, and those who, from their official situation, were best fitted to cast light on the subject, have been either prevented by pressure of business from probing it to the bottom, or have been unwilling to speak out as to a course of policy, which, since the general reaction, has been viewed unfavourably by the Public, and led them to censure severely the management of the War.

State of the Country in 1792.

To go back to the years 1790, 1791, 1792. This Country was then in profound peace, and, if there were occasional complaints, as at present, of over-competition, the condition of our trade, manufactures, and agriculture was, on the whole, satisfactory. The interest of money was moderate, and capital might be borrowed on fair terms to carry on any judicious undertaking; but there were few examples of sudden rise of price, and few Companies whose stock or shares formed an object of speculation on the Stock Exchange. This tranquil condition of our national industry, this medium between activity and stagnation, underwent a material change as the War proceeded, and as our public establishments were increased. The large demand for money by Government in the shape of loans, raised the rate of interest, and led to the suspension of many undertakings, such as canals, buildings, manufactories, for which abundant capital and a low rate of interest are indispensable. Hence the discharge and non-employment of a considerable number of persons, partly in the middle, more in the lower ranks. But that was soon balanced, and much more than balanced, by the new employment arising from the War, first in the army, the navy, and the Civil service of Government; and next in the supply of arms, clothing, naval stores, repairs of shipping, building of barracks, and the performance of many other contracts. That these employments were of great extent was evident at the time to all who had the opportunity of personal observation, and is equally evident to others, by the unparalleled expense of the war, which beginning at twenty millions sterling a year, extended progressively to thirty, forty, and eventually to upwards of fifty millions a year.

Effect in War of public loans and of large levies of men.

The number of men withdrawn from productive industry, and employed in the army, navy, and militia, was great beyond example. Already, in the year 1804, they amounted to 400,000 under arms, to whom we may add at least half as many for the manufacturers of clothing and arms, the shipwrights, the importers of naval stores, the performers of contract work for Government under various forms; making in all 600,000 men employed for account of the Public. This very large number was drawn from the able-bodied part of the population, who would otherwise have been added to our farming labourers, our mechanics, our manufacturers; in the same manner as the officers in the army and navy, and the *employés* in the Civil offices, were young men who would otherwise have been occupied professionally or commercially. Hence a great demand during the War for the service of individuals in the middle as in the lower ranks; a rise in the rate of wages, salaries, and the price of commodities in general; together with a ready engagement for almost all, high or low, who were able and willing to work. Many who, from deficient activity or mediocrity of parts, would in a state of Peace have remained unemployed, were brought by the War into situations attended with income; many of them in the public service, others in that of individuals. No wonder that under such circumstances the means of rearing a family should be augmented, and that our numbers should continue to increase. The waste of War was little felt in comparison with the number (250,000 or 300,000) added annually to our population. The rate of increase was greatest in towns, the higher wages inducing many thousands of the country youths to become mechanics and manufacturers. Now in towns, particularly in the larger towns, the working classes being so much better paid than in the country, can afford to live better, and to consume more articles productive to the Exchequer. They wear better clothing, consume more animal food, as well as more groceries, beer, and other exciseable articles. These details, homely as they are, require to be stated, because the consumption of the lower orders forms a material part of the revenue, and our object is to show in what manner and from what causes, the public income increased in so remarkable a degree during the War.

Increase of the revenue during the War.

Our taxable income.

It may be useful to attempt a short sketch of the heads of our taxable income. It consists first of the income of the upper and middle classes, and next of that of the better paid portion of the lower orders, the whole coming under the following heads:

Rent of land;
Rent of houses;
Dividends from the public funds;
Pay of the army, navy, and public offices;
Income from trade and professions; and, lastly,
The wages of the better class of mechanics and manufacturers.

Now the effect of the War and of the extended circulation of Bank notes was a great increase in the pecuniary receipts of individuals; in the rate of wages, salaries, and the price of commodities generally. This, in other words, was so much added to the money amount of the national income subject to taxation. In 1792, before the War, our national income, subject to taxation, appears not to have exceeded in money one hundred and thirty millions sterling;

Its great increase.

But in 1806, after thirteen years of war, it had risen to two hundred and twenty millions;

And eventually, in 1813, after twenty years of war, to three hundred millions!

Such was the extraordinary result of a War, conducted chiefly by means of Bank paper. In former Ages the small Republic of Holland, which, compared to other Countries, seems little more than a speck on the Map of Europe, maintained long and expensive struggles with powerful States, in particular with Spain and France; but the scale both of the revenue and public debt of Holland was but a miniature of that of England. But how were we enabled to continue so long and so enormously expensive a contest? Because, of this vast outlay nine parts in ten, or rather nineteen parts in twenty, were little more than a *circulation;* a reissue to the Public for clothing, stores, the pay of the army and navy, and other heads of expenditure, of the very large sums drawn from the Public by loans and war taxes.

Thus the Treasury received from the tax-gatherer and loan-contractor a given sum; it reissued the same in payment of stores, of personal service, or of the interest of borrowed money; and the respective parties, thus receiving sums from the Treasury, paid back great part in excise and other duties. Our taxes and our expenditure were thus a continued circulation, and had they not been so, neither this nor any other nation could have withstood them for two years; but the difficulty is explained from the time at which we see the Exchequer returning with one hand what it had received with the other; particularly when we find that no less than twenty millions a year of our expenditure were at the charge of posterity; that is, the money borrowed yearly during the War was on an average twenty millions; so that the circulation of that very large sum stimulated our productive industry without any other burden at the time than that of the interest.

Charging and countercharging in trade.

It may be useful to explain what is meant by an expression which is applicable to persons in trade under any circumstances, but particularly under such as we are now describing. The rise which during the War took place in the rate of wages, joined to a rise in the price of raw materials, such as wool or flax, led necessarily to a rise in the price of the finished article; that is, the manufacturer charged to his customer the additional sum he had been obliged to pay to his workman and to the grower of the raw material. The purchaser naturally objects to this extra demand or not, according as he may find difficulty in charging it again to the exporting merchant, or to whoever buys from him. But, at a time when prices generally were on the rise, there was little objection to an augmented charge; the principal point was to obtain the goods. In like manner our farmers, receiving a higher price for their corn and cattle, had no objection to pay back a part of their new profits to the different shopkeepers and tradesmen from whom they received supplies. It was thus that the extra price paid in one stage of a transaction was repaid to the disbursing party in the next; charging and countercharging went on in a circle; and with comparatively few objections after the exemption from cash payments in 1797 made money permanently abundant.

The Peace and general fall of prices.

Such were the causes of that remarkable state of things in which our resources seemed to increase year after year with the demands on them, and the magnitude of our financial means were as much an object of surprise to ourselves as to the nations of the Continent. But so unnatural a combination of circumstances could not last; the War came to an end, and with it our loans and War-taxes. Our army and navy were reduced; the militia ceased to be embodied; the contracts for stores were greatly lessened. The thousands and tens of thousands of able-bodied men lately drawn away for the public service, were now left quietly at home and allowed to follow a productive employment. Hence a general fall in the price of commodities, followed by the non-employment of very many persons, and by reduced wages to those who were kept at work. Corn, which had so long fetched a high price, now fell thirty and forty per cent.; the fall was equal in other articles, such as timber, hemp, flax, in every thing, in short, of which the import from abroad, long prevented by the War, was now open and unrestricted. The consequence was the failure of many thousand persons, whether agriculturists, merchants, or manufacturers, and a general complaint that though the income-tax, amounting to so much as fifteen millions a year, was taken off, the pressure of our public burdens was felt much more severely than during the War. In fact, the Public have had since the Peace as much or more difficulty in paying fifty millions a year, as had been felt in paying seventy millions during the War.

Never was there a more unexpected result. Our public men, far from anticipating financial embarrassment at a Peace, had considered it likely to be, what Peace had generally been in former Ages, a season of relief. The War had lasted so many years, that few either of our Ministers or our merchants, preserved an adequate recollection of a state of Peace. Sir Francis Baring, and the men of his day, who had witnessed our financial difficulties at the end of the American War in 1783 and 1784, were no more; we had lost Mr. Pitt also, who, as he was the only Minister who could have prevailed on the nation to incur such an enormous expenditure, was the only one capable of devising measures for lessening its eventual pressure. Lord Liverpool, Mr. Huskisson, and others of our public men who gave, or rather endeavoured to give attention to such subjects, (for the urgency of current business is too great to enable men in office to think either long or profoundly on a difficult subject,) had not, from their time of life, witnessed the state of our trade and finance at the close of the American War. The consequence was that things were left to their natural course, and no step was taken by Government to lessen the reaction, or to relieve the classes more particularly exposed to its pressure.

Not understood by our public men.

Lord Lauderdale, who had studied Political Economy, and had given a great deal of attention to the Bullion question, foresaw in the last year of the War a part of the approaching reaction. He stated in Parliament, that since the depreciation of Bank paper, twenty shillings of our currency were worth no more than fifteen in gold or silver, and he recommended that, on returning to cash payments, existing contracts should be adjusted in that proportion. There could be no doubt of the propriety of our returning, as soon as at all practicable, to cash payments, and of our getting quit of so glaring an irregularity, as that of Bank notes not convertible into coin; the question was on what terms, on what proportional scale, the reinstatement of our currency ought to take place. Had Parliament foreseen the general decline of prices that has taken place, they would probably have listened to the admonitions of his Lordship, and of others, who entreated them to pause before engaging to pay in cash without deduction, the enormous sums that had been borrowed in paper. But the close of the War was a time of general excitement; we had fought our battles with success; we had accomplished the deliverance of Europe; we had reduced France and her proud ruler to their level; and among so many subjects of self-congratulation we were little disposed to listen to unfavourable views, or to adopt negative measures. There was a general expectation among merchants, as among Members of Parliament, that the depression of trade would be of short duration; an impression which the course of events has been far from confirming.

Fluctuations in our Trade since the Peace.

Exports to the Continent in the year 1814.

The overthrow of Bonaparte in 1814, reopened to our trade the Netherlands, France, Italy, Denmark, in short every part of the Continent from which he had excluded our merchandise during several years; that is, from the time that he had thought fit to enforce the execution of his insane anti-commercial edicts of Berlin and Milan. These prohibitory decrees were coincident in point of time with our stoppage of the American trade, and under the joint effects of the two, the prices of various articles had risen to a height almost unknown in the History of trade; tea selling on the Continent for ten and twelve shillings a pound, sugar for five and six shillings. This had led to very singular expedients, such as conveying groceries and other articles into Germany by land, unloading them first at Salonichi in Greece, and carrying them, on the backs of mules and horses, through Servia and Hungary, into the heart of Germany, a distance of nearly two thousand miles. Such was the miserable waste of money and labour consequent on the struggle between the two Governments; our Ministers having put an end to the navigation of neutrals, and Bonaparte being determined that British shipping should not take their place. Happily the overthrow of his armies, first in Russia, afterwards in Germany, burst the chains by which he fettered the activity of merchants, and opened the Harbours of both the North and South of Europe, to our exports. But, as usual, the ardour of our merchants carried them too far, for they had no adequate idea of the impoverishment of the Continent. Looking on the Map at the vast extent of coast, and at the number of large cities now re-opened to our trade, our speculators considered, that if England alone consumed annually above 15,000 tons of tea, and 150,000 tons of sugar, the consumption of the Continent must be at least equal. Of the success of these adventures, the speculators had no doubt; their anxiety was to lose no time; to be the first to arrive in the Continental markets. The result however was, in general, unfortunate; the foreign buyers were wholly unable to pay the price required to indemnify the shippers in England: and since it was necessary that sales should be made, they were made at a ruinous sacrifice.

Such was the state of our foreign trade at the end of 1814. The year following was ushered in by the news of the Peace between England and the United States of America, which opened or seemed to open a great market for our manufacturers. This was a new field and regarded a class of our traders quite distinct from those who had suffered by the exports of the year before. They were, however, as full of ardour as their predecessors, and, on referring to the Custom-house returns, we find that the quantity of British goods sent abroad in 1815, was great beyond example. But the result was very unpropitious, and our merchants were now taught to their cost how greatly our Government had erred in stopping the American navigation during so many years. By doing so they had impoverished our Transatlantic customers in nearly the same manner as Bonaparte, by his tyranny, had impoverished Holland, Prussia, and

Exports to the United States in 1815.

The result unfortunate.

other parts of the Continent. The selfish and headstrong enthusiasts in this Country who, in 1807, had prevailed on our Ministers to issue the Orders in Council against American navigation, had no idea of the extent of the mischief that would recoil on ourselves. For all this we suffered severely in 1815 and 1816; our only satisfaction was that the very low prices at which our goods were sold in the United States, checked the new establishments in that Country, and showed how unavailing it was in a quarter wherein labour is so high-priced, to enter into competition with the manufacturers of England.

General distress in 1816.

Next came the overthrow of Bonaparte at Waterloo; an overthrow so complete as to give assurance of a general and long-continued Peace: hence a great reduction of the military establishments in every Country in Europe; the return of many hundred thousand men to productive employment, and a general fall in prices. Was it then matter of surprise, that so great and sudden a transition should have produced that general stagnation of business; that want of work for the lower orders; that pecuniary embarrassment in the middle and upper ranks, which will so long mark in gloomy colours the year 1816? Corn and country-produce had been at low prices during two years; many of our farmers had failed; many others were paying their rents out of their capital. Among merchants and manufacturers the decline had been equally great; and men inquired anxiously of each other from what unknown cause the high prices and prosperity of a state of War had been succeeded by such general impoverishment. On this occasion, however, our distress did not last long; favourable exchanges brought us large sums of gold and silver from the Continent; the Bank of England, and, in consequence, the private Bankers, were at ease as to money; and the bad harvest of 1816, though productive of extreme suffering to many of the lower orders, gave the farmers assurance of high prices for a certain period to come. This operated as a stimulant to the employment of country-labourers; and the course of circumstances led to a corresponding revival of industry in towns.

Revival in 1818.

Circumstances were similar during the year 1818; the demand for workmen and the rate of wages progressively advanced; funded property rose in price; the case was the same with landed property, so that this proved the most stirring and apparently prosperous season we had had for many years. It is necessary to say "apparently," because unfortunately the high wages and high prices of this interval, its large sales and liberal profits, were of short duration. Trade had, as usual, been overdone; we had imported of various commodities more than we could turn to account at the time; the speculators, at least the needy part of them, were unable to wait; goods were forced on the market, and the result was a series of losses, insolvencies, and bankruptcies. At that moment, Parliament decided on the resumption of cash payments; and although the act was prospective, and allowed the Bank considerable time to effect the change, there prevailed from that time forward, among merchants as among agriculturists, an apprehension that they would be straitened in pecuniary means, and that the prices of commodities could not be otherwise than low.

Low prices in 1819 and 1820.

Committee on Agriculture in 1821.

Monied capital becomes abundant.

The years 1819 and 1820 were thus passed in a languid, discouraging manner; in the latter the harvest proved uncommonly abundant, and the price of corn and country-produce experienced a fall. This tended greatly to the relief of mechanics and the lower ranks in towns, but as greatly to the injury of farmers, who declared loudly that with such low prices it was wholly out of their power to pay their rents. Hence the appointment, by the House of Commons, of a Committee on the state of agriculture, which sat many weeks, examined a number of witnesses, and made a long and comprehensive, though by no means a perspicuous Report. The writers of that Report took a historical view of the state of the landed interest for more than half a century, and enlarged on the prosperity which had always attended it when our merchants and manufacturers were thriving. The inference was, that the interests of traders and landholders were identified; and that it would be vain to expect relief to the one by imposing a burden on the other. The agriculturists complained of the pressure of taxes; but the Report forbade any attempt at trenching on the property of the fundholder, and encouraged the landholders, at least that large proportion of them who had to pay interest on borrowed money, to expect relief from a very different cause; from the probable fall in the rate of interest, the state of the money-market indicating an approaching reduction from five to four per cent. The expectation thus held out was realized to a considerable extent, monied capital became abundant; and in the course of 1822 and 1823, a general reduction of the rate of interest took place.

Its favourable effect on trade.

This abundance of monied capital continued and produced its usual effects; a general rise in the value of funded property, which led many persons to sell out and invest their money in various undertakings, such as the purchase of land, building houses, improving roads, or excavating canals. All this tended to create work and excite a general activity. Add to this that the price of corn having at last experienced a rise, the farmers were in some measure relieved, and enabled to circulate money as well by employing more labourers, as by making purchases from tradesmen and manufacturers in towns.

Joint Stock Companies in 1824.

The Commercial tide was now turned in our favour, and the year 1824 proved eminently prosperous. It was marked by a continued rise in the price of funded property, a general briskness in our markets, and a considerable surplus in the public revenue. The abundance of monied capital led to the formation in that year of numerous Joint Stock Companies. One of the first of these was the Alliance Insurance Company, the stock or Shares of which rose to a premium, not so much from expectation of large profits, as from the wealth of Mr. Rothschild and other leading parties in the direction, and from general confidence in their management. Next came the formation of several Mining Companies in connection with Mexico, and one with Brazil. This took place at a time by no means favourable to prudent management, for whenever money has been long abundant, the feeling engendered partakes more of confidence than is fitted to commercial enterprise. The Mining Companies formed in the first instance proceeded on fair grounds; on information which, though very imperfect, had for its basis to engage only in mines of good repute. For a time the stock or Shares of these Companies bore a moderate premium: it was not until the latter months of the year (1824) that their price began to give evidence of an abuse of prosperity. It then rose week after week, not from the receipt of any intelligence of consequence, but from the continued abundance of money and from the puerile and visionary feelings which influence the Stock Exchange, where, whenever circumstances have been for some time favourable, the example of a few leading purchasers is so often followed by the mass with indiscriminate eagerness.

The year 1825.

We are now arrived at the memorable 1825, a year in which the spirit of speculation in this Country reached a height that rivalled the excitement of the Mississippi scheme in France, or of the South Sea Company, a century ago, in England. What were the causes of such infatuation among merchants, who, in general, had considerable experience, and had witnessed the evils of reaction in the money market? It was to be ascribed to a concurrence of flattering circumstances,—to abundance of monied capital, a confidence that such would continue, a progressive rise in the public funds, and an exaggerated notion of the wealth of Mexico and Peru. The real circumstances of Mexico were little understood in England, or in any part of the North of Europe. The persons who had emigrated from Mexico after the Civil War, repaired not to this Country nor to our West Indian Colonies, but to Cuba, Bordeaux, and Spain. Cadiz and the smaller maritime towns in Spain connected with Mexico in trade were the proper quarters to obtain information; but of all the Mining Companies then formed, not one thought it necessary to resort for admonitory instruction to so distant a quarter. Their Directors had before them the flattering statements of Baron Humboldt; they had a vague but highly favourable notion of the productiveness of the mines of Mexico and Peru; and they had very little experience of the manner in which one sum of money after another is absorbed in those hazardous undertakings.

The managers of these Companies were almost equally in the dark in regard to points of vital importance at home. The abundance of money in this Country was great, but was it likely to continue, or did it not proceed in a great measure from the issues of Banks, issues necessarily uncertain and liable to be recalled whenever the course of exchange should carry our gold abroad? Questions such as these were unfortunately not put by one merchant to another; for deliberate inquiry and sober calculation were overlooked in the continued rise of funded property and of almost all articles of merchandise. Men began to think that abundance of capital was natural to a state of Peace, and that the difficulty would be in finding the means of investing it. Hence the large sums so precipitately lent to the South American States, which, whatever may be their eventual prosperity, are at present thinly peopled, badly governed, and, in many respects, in the infancy of their productive industry.

Purchases on speculation in 1825.

Such was our connection with Spanish America in 1825. It had absorbed a large amount of British capital; but the great cause of pressure on our trade at the end of that year, and the origin of the unfortunate panic, was of a different nature: it was to be sought in the purchase and import, on an extravagant scale, of foreign goods, such as cotton, wool, silk, and timber. This took place in the following manner. It is usual at the end of the year for brokers in colonial produce to report to their various friends and connections, in a printed circular, the state of the home market, and the amount of the expected supply. The import of cotton having been less in 1824 than in preceding years, and the stock on hand not great, it occurred to certain speculators that this bare state of things, joined to the great activity of our manufactures at Manchester and elsewhere, was likely to cause an insufficiency in the supply and a consequent rise of price. Hence extensive purchases of cotton were made in the Liverpool market in January 1825, and orders for further purchases were sent out to various foreign Countries; to Carolina, Georgia, Brazil, and even to the East Indies. Silk and a number of other articles were ordered in like manner; not that the supply was actually deficient but that it might become so, in the event of our consumption proceeding in an increasing ratio.

Particularly in foreign goods.

Our gold exported.

The Public were then altogether in a state to be operated on by stimulants; the prices of almost every article of merchandise had risen progressively during the preceding twelve months: hence an expectation that they would continue to rise, and that purchases made at almost any price would be attended with profit. Hence also orders were sent abroad to buy up, not only cotton, but wool, silk, and other articles; and as these orders were conveyed in the private letters of merchants, and accompanied by no act of publicity, engagements were unfortunately contracted to a great amount before one merchant became aware of the extent of the purchases of others. Suspicion of the extent was first entertained by the underwriters at Lloyd's Coffee-house, who saw in the insurances offered to them an evidence of imports to an unprecedented amount. This took place in the Summer months, but the magnitude of the purchases did not become known until the Autumn, when the goods reached this Country, and were reported at our Custom-houses. The sums to be paid for these imports were immense, the goods having been in general bought at high prices. Hence a continued drain of gold from the Bank, the export of the precious metals amounting repeatedly, in this year of wonders, to so much as a million sterling a month.

A few cautious persons had conceived alarm from a very different cause. A number of London Bankers used during the War to have discount accounts at the Bank of England; several have continued them since the Peace, but first-rate Bankers make it a rule to avoid discounting at the Bank, their own reserves being in general sufficient. But in this singular season it was observed that Banking-houses of the highest character, houses which had hardly ever been known to apply to the Bank for discount, found it necessary to do so. The cause was the continued demands on them by the country Banks in their connection: the alternative for the London house was either to withhold aid from the country Banks at the risk of making them suspend payment; or to afford supplies, by submitting to send in bills for discount at the Bank of England. They preferred the latter, and supported the country Banks, so that, though a number of the latter found their funds lessened during the Summer, no failure of consequence took place among them till the latter part of the year.

Distress of our Banks.

Many persons were surprised to find the scarcity of money begin in the country, having expected it would have shown itself first in London. But, in fact, the drain of gold was great in both at the same time; that it was not earlier felt in London was owing to the large amount of treasure in the coffers of the Bank of England, the accumulation of four years of favourable exchanges.

Such were the chief causes of the two great mercantile convulsions (1816 and 1825) which have taken place in this Country since the Peace. More than seven years have elapsed since the latter and the greater of these convulsions; but there has occurred in that long interval little to call for remark in this summary, because, in a commercial sense, its character has been nearly uniform; *viz.* sales and purchases of merchandise have taken place to a great extent, but almost always at low prices. One part of our Custom-house books exhibits the quantity, another the value of our exports: in the former there has been a progressive increase; in the latter an equally regular decline; the consequences to be expected from long continued Peace, and open intercourse with Countries in which the rate of wages and cost of subsistence are lower than in England. To put this in a clear light, we exhibit in opposite columns the respective effects of Peace and War on the price of commodities.

Effects of Peace and War on the price of commodities.

War.	Peace.
The rise of prices during the War was caused as follows:[*]	The fall of prices since the Peace has been caused by,
1st. The demand for men for the public service raised the rate of wages, and the demand for money raised the rate of interest, both of which tended greatly to raise prices.	1st. The cessation of the demand for men and money for the public service.
2d. The insufficiency of our crops caused by an unusual number of bad or indifferent seasons, (*viz.* 1794, 1795, 1799, 1800, 1804, 1809, 1811,) and by the obstacles to import from the Continent.	2d. Since the Peace the number of bad or indifferent seasons (1816, 1828, 1829, 1830, 1831) has not been so great; and the only obstacles to import from the Continent have been our Corn Laws.
3d. The increase of taxation.	3d. The taxes have been reduced by more than twenty-five millions a year since the peace.
4th. The great expense of freight, insurance, and other charges on the import of foreign goods.	4th. Freight, insurance, and other import charges were reduced more than half by the peace.
5th. The depreciation of our Bank paper, particularly in the last five years of the War.	5th. Our Bank paper rose to a par with coin in 1816, and, with the exception of one interval, (1818 and 1819,) has ever since maintained an equal value.

Much has been said of the fall in prices in England from the contraction of our paper currency, and of their fall in Europe generally, from the reduced supply of the precious metals during the last twenty years. Each has been serious in its operation; but the great and overpowering cause of the decline is the absence of a demand by the Governments of Europe of either men or money for the purposes of War; the restoring to productive employment the many millions of capital, the hundreds of thousands of able-bodied men who were formerly withdrawn from it. The prospects in regard to the price of commodities, of every class, whether agriculturists, manufacturers, or merchants, are all mainly dependent on the probability of continued Peace. Any plan for the relief of the productive classes, for lessening the pressure which has long borne, and still bears, so hard on them, must have reference to and depend on the prospect of the nation in that respect. We shall, therefore, bestow a few paragraphs on an examination of this question: on the causes of the Wars which during the last century and a half have so seriously affected our commercial situation; and on the circumstances which justify a hope of their less frequent occurrence in future.

Prospect of continued Peace.

Causes of former Wars.

It was not until the Revolution of 1688 that this Country took a decided part in Continental politics, and began to carry on Wars on a large and expensive scale. This sacrifice our increasing resources fortunately enabled us to make, and it was strongly called for by the state of foreign politics. Louis XIV. had acquired a preponderance which threatened the independence of Europe; Germany and Holland were unable to keep that restless Prince within bounds; an extended coalition was required; and England was invited to be one of its leading members. In our own days, a similar dread, first of anarchy from the Revolution, afterwards of a general usurpation by Bonaparte, led us to make unparalleled sacrifices in opposing France. But circumstances are now greatly altered: France is still suffering from a series of disastrous contests, and has a population sorely divided in political feeling. Peace is indispensable to heal the wounds inflicted by the Revolution and the tyranny of Bonaparte, while as to national union the present generation and probably the next must pass away ere it can be restored. And even were there to arise in France a Government inclined to War, the power of that Country compared to ours is no longer such as to be a subject of serious alarm. A century ago, Great Britain and Ireland bore to France, in point of population, the proportion of only 45 to 100; nor was the proportion of national income much more in our favour; but so much greater has been the ratio of our increase in the last hundred years, that, in population, we now hold the proportion of 75 to 100, and in taxable income of 100 to 100. These are not mere calculations on paper; they are actual results founded on substantial and permanent grounds; on the advantage of our insular position; our extensive canals; our mines of coal and iron; our superior capital; our formed habits of industry. These have been the causes of the surprising increase in our resources during the last century; and they promise a still greater increase in that which is now in progress.

Surprising increase of our resources.

At what period did the effects of this increase in our wealth and numbers become apparent in our military exertions? To pass over the brilliant era of 1759, when the talents of Lord Chatham may be considered to have turned the scale in our favour, and to fix our attention on 1778 and the following years, when France, Spain, and Holland had taken part with America against us, we found our resources, though wielded by so feeble a Minister as Lord North, sufficiently great to conduct us with honour out of the contest. In the Wars of the present Century, the surprising increase of our national means was put beyond all doubt, and in fixing the conditions of the Treaties of Peace of 1814 and 1815, our Ministers gave an assurance to the World, that they no longer thought it necessary for the safety of England that the power of France should be impaired. On those occasions, our allies would readily have effected a dismemberment of her territory, by separating from her such Provinces as Alsace, Lorraine, Franche Comté, and French Flanders: but our Ministers knew the augmented strength of this Country, and that France was no longer an overmatch for us. Instead, therefore, of seeking to weaken France, they appear to have considered the maintenance of her integrity essential to the equilibrium of the Commonwealth of Europe.

---

[*] See in the Supplement to the *Encyclopædia Britannica*, the heads *England* and *France*.

Disposition of the French.

In the situation of the French, various circumstances are in favour of continued Peace. The ship-owners, insurers, and other classes, who in this Country derive great temporary advantage from a state of War, are of very little account in France: the same holds in regard to the monied interest, the merchants and traders generally; all of these are on a footing much inferior to that which the same classes now hold in England, or held in Holland in the day of her prosperity. The great majority of the French are agriculturists, and a state of War can hold out little prospect of rise of price to the farmers of a Country which imports very little, because in nine years out of ten its produce is equal to its consumption. When to all these inducements to Peace we add, that the levies for the French army are still made by that most odious law, the Conscription, a law which, operating by ballot, keeps parents in continual uneasiness, and takes young men from their homes at a time at which they ought to enter on employments for life, we shall have little difficulty in believing that a renewal of War would be extremely repugnant to national feeling in France. It is, we believe, equally repugnant to the views of the reigning Sovereign, who cannot but be aware, that with the great political divisions now existing in France, and which are likely to continue during the present generation, a contest with this Country would be replete with danger to his sway.

Colonies no longer a cause of War.

Another fertile source of War during the last century, the desire of possessing Colonies, has also ceased; Mexico, Peru, Chili, Brazil, are now open to every flag, and not likely to become a cause of War between the Powers of Europe. We have learned to our cost, how greatly they were overrated, and that Ages must elapse ere they become really valuable. And those among us, who, dazzled by the increase of money incomes during the late contests, consider a state of War conducive to national wealth, will do well to bear in mind the distressing reaction of the last eighteen years. The War, it is true, added largely to the income of our agriculturists, merchants, and manufacturers, but have we not, in almost every year since 1814, witnessed the successive disappearance of those splendid additions? Their foundation was temporary; resting on high prices and the demand of Government for men and money, they ceased together with their cause; involving many classes of the community in all the evils of a transition from affluence to poverty, from hope to despondency. The more enlightened part of the nation has now become aware of the temporary nature of such gains and of the immense loss attendant on such reactions. Our public men may therefore be assured of its support in that pacific course, by which alone they can hope to heal the wounds of Ireland, or lighten the burdens of England.

Effect of continued Peace on our trade.

Assuming it, therefore, as probable, that a state of Peace will be maintained for a considerable time, we proceed to the interesting, it may be almost said, the anxious question, how far the reduced rate of prices attendant on Peace, will affect the state of our trade. The first point is to ascertain to what extent our produce and manufactures have undergone reduction in price, and in this we shall be aided by the returns of our Custom-house. There is, as is well known, a double registry of our exports in the Custom-house books; one founded on the market price, or the value as declared by the exporting merchants; the other a record of quantity rather than of price, the value affixed to each kind of goods being the same year after year, and taken from an official list or standard fixed so far back as 1696. In this standard certain articles, such as woollens, linens, cottons, are computed at so much by the yard or piece; while others, such as hardware, leather, soap, are reckoned by weight. The result of this calculation is then entered in the Custom-house Ledger, and as details of quantity would be uninteresting to the Public, the rule at the Custom-house is to print nothing relative to weight or dimensions, but to give the result in money, and in the shortest form, *viz.* in one line for each year; thus,

Official value explained.

British Produce and Manufactures exported in the following Years, calculating first the quantities and afterwards their amount in Money, according to the official standard of 1696.

WAR.		PEACE.	
1810.......	£45,869,859	1826.......	£40.965,736
1811.......	32,809,671	1827.......	52,219.280
1812.......	43,243,173	1828.......	52,797,455
Total of three years of War	121,922,703	Total of three years of Peace	145,982,471
Annual average	40,640,901	Annual average	48,660,823

Exports greater in quantity

These sums being merely an index of quantity, it follows, that in that respect, there is, since the Peace, an increase of more than 20 per cent. in our exports; but in their value the result is very different.

Value, or Market Price of the abovementioned exports, as declared in the respective years, by the exporting Merchants.

WAR.		PEACE.	
1810.......	£49,975,634	1826.......	£31,536,723
1811.......	34,917,281	1827.......	37,182,857
1812.......	43,657,864	1828.......	36.814,176
Total..	128,550,779	Total..	105,533,756
Annual average	42,850,259	Annual average	35,177,918

but less in value.

This return exhibits, in the first instance, a decrease in the money value of our exports since the latter years of the War, of nearly 30 per cent. And as we have seen that our exports in late years are greater in quantity than during the War by 20 per cent., it follows that the total decrease, in the money value of British produce and manufactures exported, is nearly 50 per cent. compared to our prices twenty years ago; that is, when foreigners pay for our goods in money, we receive only £50 for articles which twenty years ago produced £100; a formidable reduction truly, but fortunately little more than nominal, since the articles supplied by foreigners in return, such as wool, cotton, silk, lead, have fallen in an equal, or nearly an equal proportion.

It may be interesting to our readers to mark the steps in this progressive decline of prices; and for this purpose we shall select by far the most important article in our list of exports,—our cottons. In the year 1814, the market price of our cottons was nearly the same as the rate at which they are valued in the Custom-house ledger; that is, a given quantity of cotton goods, amounting, by the official standard of valuation, to £100, might have been bought in the market for £104. Observe how constantly, and even rapidly, the market price has declined since that time.

Decrease in the price of cottons.

Cotton Goods exported.

Years.	Valuation by the Custom-house Rates.	Market Price.
1814	£100	£104
1815	100	90
1816	100	80
1817	100	70
1818	100	77
1819	100	72
1820	100	67
1821	100	64
1822	100	59
1823	100	56
1824	100	56
1825	100	57
1826	100	49
1827	100	47
1828	100	46

We find here a decline, and to a considerable amount, in every year, except in the two seasons of excitement, 1818 and 1825. In other articles, the fall of price has not been altogether so great as in cottons; thus

Manufactures exported; comparative value of the same quantity at different periods; viz. in 1814 *and* 1828.

Of other goods.

	Market Price in 1814.	Market Price in 1828.	Average Annual Amount exported in late years, as declared by the Merchants.
Hardware	£100	£66	£1,300,000
Woollens	100	60	5,000,000
Linen	100	58	2,000,000
Silk	100	48	300,000
Cotton	100	44	14,000,000
Leather alone has nearly maintained its price	100	98	300,000

This fall of price, however, is a loss only in some respects; for if we inquire into the manner in which it has taken place, or under what heads of charge it ought to be appropriated, we shall find it to have arisen from.

A reduced price of wool, cotton, silk, and other raw materials;

The manner of such decrease.

A reduction of wages to the workmen, and of profit to their employers;

Improvement of the machinery employed, and a consequent cheapening of manufacture from that, as well as from the greater subdivision of the work.

As to the first of these heads, the supply of raw materials continues abundant even at low prices. Cotton has declined ever since the Peace, yet the import increases, though the price is now only half of what was, some time since, accounted the lowest cost of its production. Of wool, the import from the North of Germany alone is now much greater than it formerly was from all foreign Countries together; and of silk, our Indian territory offers a progressively increasing supply. Such are the consequences of improved modes of cultivation, and of the application to commercial objects of the vast amount of labour and capital formerly absorbed by War.

Reduction of price from such a cause, or from improvements in machinery, is evidently a public benefit; but a decrease in the wages of workmen, or in the profits of their employers, is very different, and has, from its long duration, given rise to much distress. Relief is to be looked for, not from increase of income to either the employers or their workmen, such being altogether unlikely in this season of profound Peace, but from a reduction of expense; a fall, as Adam Smith would have termed it, in the cost of food, clothing, and lodging. This reduction has already taken place to a considerable extent: the decline in the average price of wheat in this Country since the Peace having been in the proportion of three to two; (from 90*s.* to 60*s.* a quarter;) a fall so great as to have caused the gradual disappearance of most of the capital accumulated by farmers during the War, and to have produced a heavy deduction from the property of landlords. In what manner has this great change affected our manufacturers and traders? In one sense it has been advantageous, in another the reverse; it has lessened to them greatly the expense of subsistence, but it has considerably narrowed the consumption of manufactures and merchandise by our now impoverished agriculturists. The latter are in the present year (1832) in the same depressed state as ten years ago, and will do well to limit their expectation of relief to two points: the probable fall in the rate of the interest of money; and a further reduction in farming charges; in a return, in short, to the scale of 1792.

Reduced price of corn: its effect on trade.

Many of our landlords and farmers are, as is well known, largely indebted for money borrowed on mortgage and other security. The Committee on the state of agriculture in 1821, aware that such engagements were of great extent, and that in time of Peace repayment of the principal was not to be expected, confined its attention to the prospect of the agriculturists paying the yearly interest, and enlarged on the abundance of monied capital as likely to lead to a reduced charge for its use. The authors of that Report judged soundly, so far as regarded our political prospects; they knew the anxiety of our public men to maintain Peace, and inferred from the state of France, that it was very unlikely that the Government of that Country would for a long time incur the hazard of War. The rate of interest declined, and borrowers obtained an abatement in general from five to four per cent.; but in a few years it rose again, in consequence of the infatuation of our Countrymen, on the opening of Spanish America. The sums so imprudently advanced to that Country in loans and mining speculations, or paid to foreigners for our imports in 1825, exceeded all anticipation; and in conjunction with political disquietude, have ever since kept our surplus of disposable capital within narrow limits. But for some time back, circumstances have been indicative of its renewed abundance, and as it is very unlikely that our merchants will repeat the imprudence of sending large sums abroad, the agriculturists may entertain a hope of the return of the advantages of 1822, without the reaction which was then incurred by entering on a new and unknown field.

Having now completed the Historical notice of our trade, we proceed to give an account of its present state; beginning with our Manufactures, a subject of sufficient interest to claim a minute and copious exposition.

MANUFACTURES OF ENGLAND; THEIR PROGRESS AND PRESENT STATE.

Woollens.

The woollen manufacture; its early state.

We begin our sketch of the National Manufactures with the Woollen trade, as well on account of its importance as because wool was the chief article of export from England in early times. It continued to be so for several centuries after the Norman Conquest, and was the result of two causes; the great extent of our pastures, and the inability of our population to manufacture into cloth the quantity of wool annually produced. Our pastures are superior to those of France, Germany, or Poland, because in England rain is of more frequent occurrence, and droughts are comparatively rare; while on the Continent, at least in many inland parts, the grass becomes dry and parched during the Summer months. As to the state of our population, during the Middle Ages it was almost all resident in cottages; in other words, our agriculture was so rude and the personal exertion of the husbandman was so little aided by machinery or suitable implements, that the labour of no less than four persons in five was needed in the fields to provide the subsistence required by the community at large. Of the smallness of our towns an estimate may be formed from the following Table.

Population of England in 1377.

Population of the Chief Towns in England from a Census in 1377.

London	35,000
York	11,000
Bristol	9,000
Plymouth	7,000
Coventry	7,000
Norwich	6,000
Lincoln	5,000
Sarum, Wiltshire	5,000
Lynn	5,000
Colchester	4,500
Canterbury	4,000
Beverley	4,000
Newcastle on Tyne	4,000
Oxford	3,500
Bury, Suffolk	3,500
Gloucester Leicester Shrewsbury	each somewhat more than 3,000

Such was the limited population of our towns in the XIVth Century: in the XIIth and XIIIth it was still smaller, while Flanders could boast of considerable cities in Bruges, Ghent, Antwerp, and Brussels. Hence the superiority of the Flemings in weaving as in other Arts: their looms were better, their workmen were more expert, their employment was more subdivided; there was, in short, a more ready supply in their towns of all things auxiliary to a complicated process of manufacture. English weavers, residing in hamlets or villages, and indifferently provided with the requisites for manufacture, could prepare only coarse cloths; the finer were made in the Netherlands, and sent to England and France for sale. The money thus obtained by the Flemings for the cloths made of our wool supplied them with a fund for the purchase of further quantities of the raw material. Such was the routine of sale and purchase between the two Countries during several centuries, but our Countrymen became in time desirous of extending their share of the manufacture. Accordingly, in the middle of the XIVth Century, (in the active reign of Edward III.,) weavers from Ghent were invited to settle in England and to introduce the art of making the finer woollens. They were established at first in villages in Kent and Essex, not far from London; not that the spots in question had any marked advantage as to fuel or water-power, the great considerations in the present Age; but on account of their vicinity to conveniences of another kind, as by the Thames they could communicate on one side with London, on the other with the Continent.

The inland Counties would not in that early Age have been suitable for such establishments, being devoid not only of canals but of roads, and presenting neither opportunity of sale nor facilities for manufacture. But in course of time those Counties became greatly improved, and the woollen manufacture extended to the more remote parts of the Kingdom; first to Gloucestershire, where labour and fuel were cheap and wool was to be purchased at the first hand; and eventually to the West Riding of Yorkshire, where to all these advantages was added the convenience of waterfalls for moving machinery.

Slow progress of this manufacture.

The extension of the woollen manufacture of England has been very gradual, because it was long carried on by insulated workmen, and received little aid from the mechanical discoveries and inventions which have caused so rapid an increase in cotton-works. Another cause of its slow increase in former times, was that the sale of the fabric was long confined to the home-market. France, Germany, and Belgium made woollens for themselves; it was not till after 1700 that the export of English cloth to Portugal and Holland became considerable, or that our North American and West Indian colonies acquired so large a population as to render them customers of importance. At the time in question, (1700,) the value of our woollens sold for home-consumption was computed not to exceed five or six millions sterling; that of our exports was between two and three millions; in all eight millions. In the course of the hundred years that followed, the quantity made for the home as for the foreign market appears to have nearly doubled, and to have formed, in 1800, a total value of about seventeen millions. At present, (1832,) the value of our woollens exported continues nearly as thirty years ago, about five millions yearly, but that of our home-consumption may be computed at seventeen or eighteen millions, making a total yearly value of twenty-two millions or upwards, the quantity consumed at home having naturally increased in proportion to our population.

Value annually made in England.

Price of our woollens.

Next as to the price of our woollen cloths at different periods of our History, the fluctuations have been less than is commonly imagined. In fact, if we pass over the temporary enhancement which in this, as in almost every article, prevailed during the Wars of the French Revolution, we shall find the money price of woollens to have been nearly uniform for more than a century and a half. Of this we have the means of judging by comparing the present prices with what is termed the official value, or scale of prices adopted in the year 1696, for the purpose of computing the value of our exports. So great has been the fall in the cost of wool and woollen cloth since 1815, that at present (in 1832) the price of either in money is lower than it was a hundred and forty years ago; it must be admitted, on the other hand, that the cloth is lighter and less durable. The wages of the weavers and other workmen are higher, but that additional expense is balanced by the greater aid we now derive from machinery, and the saving in the consumption of wool. The French have not yet made an equal reduction in the quantity of the raw material; they use considerably more than our weavers in a given length of cloth, and their woollens consequently are both thicker and heavier.

Exports to America.

The United States of America were long the chief foreign market for our woollens, and as their population was in a state of rapid increase, they purchased more after their separation from us in 1783 than at the time they were our colonies. The first blow given to this great branch of our exports, was by an act of our own Government; by the Orders in Council of 1807, which, by stopping the foreign trade of the Americans, deprived them of the means of purchasing and obliged them to manufacture for themselves. Establishments were accordingly formed for that purpose in the United States, and a large amount of capital was invested in them, after which it became in a manner obligatory on their Government to support them. That could be done only by imposing heavy duties on foreign woollens, particularly those of England; duties which formed a feature unfortunately too prominent in the American tariff of 1828, and which are still persisted in to the incalculable injury of both Countries.

Seats of the woollen manufacture in England.

Next as to the chief seats of this manufacture in England, and the number of persons employed on it. Though the value of the woollens made annually is not nearly equal to that of our cottons, the number of persons employed in the former is greater, because machinery is less used. The mechanical improvements of the past and present Age have been applied in the first instance to cottons; to woollens later and less extensively. As to the ports for the export of woollens, London was long the principal, but Liverpool has taken the lead in that respect since the extension of canal navigation and the great increase of the comparatively neighbouring towns of Leeds, Halifax, and Wakefield. The West Riding of Yorkshire, which, half a century ago, was supposed to supply a third of the woollens made in England, may now be considered as furnishing fully the half. Wiltshire, Gloucestershire, and Somersetshire, the other seats of this manufacture, have been nearly stationary; that is, without decreasing their respective quantities, they have had but little share in the great augmentation which has taken place during the last fifty years.

Supply of wool.

As to the supply of the raw material at home, the last century has witnessed a great increase in the productiveness of our pastures, in the size of our sheep, and, consequently, in the weight of the fleeces. None of these, however, have advanced in an equal degree with our population, with the number of the buyers and wearers of our cloths; so that notwithstanding all the improvements in the mode of preparing wool, and the reduced weight that now suffices for the same extent of cloth, a great increase has taken place in the import of the raw material. In former times, the only wool brought to England in large quantities was from Spain, a Country possessing in its mountains and valleys a great variety of climate and pasture grounds: the finer qualities of Spanish wool were useful, and indeed requisite for mixture with our own growth.

Import of foreign wool.

From Spain.

About the year 1700, the import of Spanish wool averaged about one million pounds annually; it increased steadily, but slowly, till towards the year 1775, when a rise in the price of English wool and an extension of the manufacture caused a continued increase of import, so that about 1800, the Spanish wool annually brought to this Country weighed about four million pounds. It has continued in some degree to increase, and may be said to have reached for some time back six million pounds a year; a large quantity certainly, but bearing no proportion to the surprising augmentation of our import from Germany.

From Germany.

That Country, formerly of so little account in the supply of wool, now annually sends us from twenty to twenty-five million pounds weight, so greatly has the management of its flocks improved in the present Age, particularly in Saxony. Altogether the foreign wool imported into England at present is about thirty million pounds a year. Our home-growth being subject to no duty or official inspection, its amount can only be guessed at from the number of our sheep, and the average weight of their fleeces. If, as has been computed, the growth of wool in Great Britain and Ireland be so much as one hundred and fifty million pounds, the total of the wool used in our manufactures is about one hundred and eighty million pounds weight a year, its value about £12,000,000 sterling.

The export of English wool, long strictly prohibited, has been free since 1825; it averages at present about three million pounds, and is made chiefly to France and the Netherlands.

New South Wales and Van Diemen's Land now send us a yearly supply of wool, in quantity about two million pounds; the quality remarkably good. It is exempt from duty, while our imports from Germany, Spain, and other foreign Countries, are subject to a duty of a halfpenny or penny per pound, according to their quality.

Linens.

Linen

We come next to a manufacture of as ancient, or nearly as ancient date in England as woollens, but of inferior importance in a national view. Though our climate is as favourable to the growth of flax and hemp as that of the Countries in which these products have been most cultivated, such as Flanders, Germany, or Livonia, linen has not at any time ranked among our principal manufactures. If of the common qualities enough for home-consumption has been prepared in England, the finer qualities have, in general, been imported; in former times from the Netherlands, but for a century and upwards from the North of Ireland.

In Ireland.

Into Ireland, the cultivation of flax and weaving of linen were introduced on a large scale above one hundred and fifty years ago, and have ever since been patronised by Government. Liberal bounties were long paid on the export of linen, and what was of far more importance than a bounty, the consumption of England, as regarded the finer qualities, was supplied by the Irish manufacturers. The quantity of linen imported from Ireland to England during the last forty years has annually amounted to thirty, forty, and forty-five millions of yards, a part of which was re-exported, but a far greater part retained and consumed at home. The average value of this yearly supply from Ireland amounts, even at the reduced prices of late years, to two millions sterling.

In Scotland, the manufacture of linen has, in general, been confined to the coarser qualities. On these, also, a large bounty on exportation was given during nearly

In Scotland.

a century that they might be enabled to maintain in America and other foreign Countries, a competition with the linens of Silesia and other parts of Germany, which had taken a lead in the market, being both good in quality and moderate in price. Bounties, it is now admitted, are, in nine cases out of ten, impolitic, and it had, perhaps, been better to have left our linen, like our cotton manufacture, to its natural course: the effect, however, of the aid from Government has been to establish linen-weaving on a very large scale in Great Britain as in Ireland, so that now that all bounty on linen is withdrawn, our Countrymen can continue the competition with the advantage of improved machinery, of workmen long practised in their tasks, and of large sums of capital invested in the business.

Principal seats in England.

In England, the chief seats of the linen manufacture are at Leeds and Barnsley in Yorkshire, and in towns of less extent in Lancashire and Cumberland. In Scotland, they are in the Eastern Counties, at Dundee, Arbroath, and Montrose. In Ireland, the seat of the linen manufacture is in the North, and the weavers live generally in detached cottages; but at Leeds and in Scotland, the business has for a considerable time been carried on in factories or collective establishments for account of mercantile houses. The latter having the command of capital, a subdivision of employment, and the various other advantages of extensive cooperation, seem likely to prove, or rather have already proved, an overmatch for the cottage system; so that Ireland can scarcely hope, under present circumstances, to increase her products, particularly in the more common qualities.

Annual value.

The increase in the quantity of our linen annually manufactured has not been by any means in proportion to our population, on account of the surprising extension of our cotton manufacture during the last fifty years. The total value of the linen made annually in Great Britain and Ireland is at present about twelve millions sterling, of which two millions are sent abroad; the coarser sorts going to the West Indies for Negro clothing. As to the raw materials, both flax and hemp are considered by agriculturists as exhausting crops; they are, consequently, much fitter objects of cultivation in Countries like Prussia, Courland, or Livonia, where population is thin and corn low priced, than in England, where the farmers find consumers of corn in abundance almost at their doors. Our imports accordingly have long been on a great scale; of late years they have amounted to about twenty thousand tons of hemp and forty thousand tons of flax, three-fourths of both being from St. Petersburg, Riga, Revel, and other Russian ports in the Baltic and Gulf of Finland.

The Cotton Manufacture.

The history of the cotton manufacture in England differs materially from that of the woollen or linen: its introduction was much later; its extension has been far more rapid. Indeed, the progress of the cotton manufacture in England during the last sixty or seventy years is the most remarkable event in the history of our productive industry. About the year 1700, the total import of the raw material did not exceed five thousand bags or bales; during many years its increase was slow, but in the early part of the reign of George III. the invention of carding machines and spinning jennies greatly extended the manufacture, so that in 1775, our average import of cotton became nearly 18,000 bales.

By the end of the next twenty years, *viz.*
in 1796, it averaged 100,000 bales or bags;
in 1801 .... above 150,000
in 1806 .... above 200,000
in 1810 and 1811 above 300,000
in 1816 .... above 370,000

since which date it has continued to increase every year, and at present (1832) exceeds the surprising number of 800,000 bales, the average weight of which is not less than three hundred pounds each.

The weaving of cotton first practised in India.

As the cotton plant requires a great degree of heat to bring it to maturity, and India was one of the Tropical Countries which was peopled at a remote date, we may consider it to have been one of the earliest seats of the cotton manufacture. It certainly has been so since the earliest records in authentic History, for cotton cloths appear to have formed an article of export from India to Europe at the time that the Indian trade was carried on by way of the Red Sea and Thebes in Upper Egypt. The lightness of these cloths made them easy of transport, while the low wages of workmen in India prevented attempts in Europe to rival this manufacture during many Ages, in short until the towns of modern Italy acquired considerable population. Even their efforts hardly deserved the name of rivalship, so superior were the fabrics of the Hindús; and it was not until half a century ago that the improved machinery of Great Britain enabled our workmen to balance the cheap labour of the East.

Progress of the manufacture in England.

We read in printed works of cotton manufactures at Manchester, so long as two centuries ago; but these were cottons only in name, the raw material being wholly wool, and the name of cotton given to the cloth from its resemblance to the cottons made in India and Italy. Wool ceased to be used in this manufacture seventy years ago, but even then the process of preparing this article for a market was very primitive. The cotton weavers in Lancashire, like the linen weavers in the North of Ireland, lived in detached cottages, and were in the habit of going to market in the neighbouring town, first to purchase thread, afterwards with the finished web for sale. They thus received very little aid from shopkeepers or dealers in towns during the time the weaving was in progress. But about the year 1760, the Manchester dealers, finding the demand for cottons increase, came forward to assist the weavers so far as to supply them with thread, or if they preferred it, with raw cotton to be spun into thread by the weaver's family; engaging at the same time to be the purchasers of the webs at a given price. The workmen were thus considerably relieved, being assured of a market for all or almost all the cloth they could get ready; but spinning by hand being necessarily tedious, the quantity of cottons made continued to be very limited. At last, in

Mechanical inventions.

1767, an ingenious person, named Hargraves, invented the spinning jenny, a machine which from the first enabled one person to spin eight threads with the same ease as one, and which was eventually so simplified and improved as to enable a boy or girl to work above one hundred spindles.

This machine, however, was fit only for spinning the weft or cross threads of a web, and had not the power of giving the firmness or hardness required in the warps

Ark-wright's discoveries.

or running threads; but that great desideratum was soon after supplied by the "spinning frame," the invention of Mr. (afterwards Sir Richard) Arkwright, which spins a vast number of threads of any degree of fineness and hardness; leaving it to the person in attendance only to supply the machine with cotton, and to join the threads when they happen to break. For this most important improvement a patent was given to Arkwright; its exclusive use during the period of the patent laid the foundation of the vast fortune of his family; and on its expiring in 1785, its general adoption greatly extended the cotton manufacture throughout the Kingdom.

The power loom.

One of the next improvements of consequence was the introduction of the mule jenny, a compound of the spinning jenny and spinning frame. All these inventions related to spinning, and surprisingly extended the quantity of yarn. The object then in request was machinery for weaving, and that was sometime after supplied by the most remarkable of all these inventions, the power loom, or substitution of mechanical for manual labour in weaving. Power looms during the last fifteen years have been multiplied to almost incredible numbers: they have, it is true, caused a serious reduction in the wages of weavers, and, consequently, a great deal of individual distress, but, in a public view, they have been highly advantageous. Without them, it would not have been practicable to have increased so rapidly as we have done the quantity of cottons made in this Country, or to have competed so successfully with the lower wages of foreigners.

Import of cotton wool.

Cotton in former times was imported from the Levant, chiefly from Smyrna; afterwards from our West Indian colonies, but from these the supply has been all along limited. Carolina and Georgia did not begin the cultivation of cotton until a recent date, *viz.* after 1790, but it has since been extended in these States in a surprising degree. Of late years, the South Western States, New Orleans, and Alabama, have greatly increased their cotton cultivation, so that the total yearly export from the United States of America now exceeds eight hundred thousand bags of about three hundred pounds each, of which above five hundred thousand bags are sent to England. Next in the supply of cotton come Brazil, the East Indies, and, during the last ten years, Egypt.

Quantity manufactured.

It is usual to compare the extent of manufacture in one year with that in another by the number of bags consumed or wrought up weekly by our manufacturers. In the year 1824, the number of bags so wrought up was about 10,000 a week; in 1827, it had increased to more than 12,000; and it now exceeds 16,000 a week! Comparing these quantities with the consumption of the years 1816 and 1817, we find that the quantity of cottons manufactured in Great Britain has more than doubled in the course of twenty years; but so great has been the reduction in the cost of the article that the money value of the vast quantity now annually made (between thirty and thirty-five millions sterling) is not much above that of the far smaller quantity prepared in 1817.

Decline of price; its causes.

This great fall of price has been owing to several causes; partly to the reduced cost of the raw material, and successive improvements in machinery. The decline in cost of the raw material has been so great that the pound of cotton yarn which in 1814 cost one shilling and sixpence, is now supplied at seven-pence or eight-pence. In all our manufactures there has been a large increase in quantity and decline in price since the Peace; but the difference is greatest by far in cotton. In woollens, silk, leather, and other articles, the increase in the quantity annually made since the Peace has borne a proportion to the increase in our population, *viz.* about thirty per cent.; but in cotton the increase has exceeded one hundred per cent., so greatly is the use of cottons extended in this Country, South America, and India.

Another remarkable feature in our cotton trade is the magnitude of the export compared to our home-consumption. Of the woollens made in Britain the proportion sent abroad is a fifth or sixth; of our hardware the proportion is somewhat more; but of cottons it is fully half. The reason is that they are sent not to a few particular Countries, but to all parts of the World. Taking the number 40 as the integer of our exports of cotton and cotton yarn, the proportions of the different Countries will be as follows:

Countries to which we export cottons and cotton-yarn.

West Indies	5
Brazil	5
Spanish America	4
United States and British North America	4
East Indies	4½
Africa	1
The Levant	1½
Germany	4
Italy	3½
Portugal	2½
Spain	2
Netherlands	1
Other parts	2
	40

Germany and most parts of the Continent of Europe manufacture such articles as woollens, leather, linen, hardware, to the extent of nearly the whole of their consumption, because manufactures in those branches were established in the respective Countries several centuries ago, in times when England had no marked superiority over her neighbours. But cottons came into demand at a time when our productive industry was in an advanced stage, when our capital had become large, our towns populous, our machinery powerful, and fuel abundant and cheap in almost all our towns, from the extent of our canals.

These are the causes of the success of manufactures, and in these the different Countries of the Continent, even the Netherlands and North of Italy, whose population is dense, and their wealth of old date, are greatly inferior to England: hence the far greater extension of the cotton manufacture in this Country.

Cotton manufactures abroad.

The cotton manufactures of France were very considerably extended about twenty years ago. Labour in that Country is still somewhat cheaper than here, but fuel is dearer and the machinery less complete. The amount of cottons annually made by the French is consequently stationary, and forms not quite a third of that which is prepared in Britain; nor are they likely to gain on us in the race of competition, for they cannot supply foreign markets at equally low prices. The same reasoning holds in regard to the cottons of the Netherlands, Germany, and Swisserland: in all those Countries establishments were commenced with alacrity during the War, and in all it is now found very difficult to withstand English competition even when our goods are subjected to an import duty. The dearness of provisions in England during the late Wars, and the high rate of wages, were the main grounds of the expected success of foreigners; but these disadvantages have gradually given way, particularly since 1827, when our Corn laws were modified, and the cost of provisions in England was brought so much nearer to that of other Countries.

Increased population of English Cotton manufacturing districts.

The consequence has been a continued increase in the population of the cotton manufacturing districts. According to the last census, that of 1831, the number of inhabitants in the chief towns was as follows:

Manchester and Stockport	178,000
Bolton (Great and Little).....	40,000
Oldham	32,000
Blackburn	27,000
Wigan	21,000
Bury	15,000
Warrington	16,000
Preston	33,000
Glasgow and suburbs........	202,000
Paisley	60,000

In most of these places the increase of numbers during the last seventy years has been in the remarkable proportion of nearly four to one! Glasgow has an extensive and varied trade distinct from the cotton manufacture, but in all the other towns the cotton trade, in one shape or other, is the main spring of local activity. The total number of persons employed in it is not ascertained, but amounting probably to 400,000, would be far greater, did not machinery perform so much of the work in every stage. To conclude, this branch of our productive industry has more than any other enabled us to bear the unparalleled burdens of the times; and it happily promises to continue to be one of the pillars of our National wealth; no other Country, whether in Europe, America, or India, possessing advantages for conducting it to be compared to those of Great Britain.

Iron and Hardware.

Early state of the manufacture of iron.

Of all our great branches of manufacture, that of iron has been, next to cotton, the most remarkable in its increase. Iron-ore was known to exist in different parts of England several centuries ago, and began to be smelted in a few situations, such as the Forest of Dean in Gloucestershire, where wood fuel was abundant and in the vicinity of the mines. The demand for iron increasing, the consumption of the wood became so considerable, as to induce the cautious Ministers of Queen Elizabeth to restrain it by Act of Parliament. The great desideratum now was to discover whether coal could be made to answer the purpose of wood fuel in smelting iron, and so early as the year 1619 a patent was granted for the use of coal for that purpose. But a very long time elapsed ere the existing prejudices and obstacles to the use of coal were removed. The works of the first patentee for coal were destroyed by assemblages of the people, who had been formerly employed in cutting and carrying wood fuel; and other iron-masters were deterred from following his example. The process of smelting by coal thus remained in a rude state, and there prevailed a general belief that iron so smelted was of far inferior quality to that which was prepared by wood or charcoal. But as the demand for iron increased with our population during the XVIIth and XVIIIth Centuries, the consumption of wood became so alarming as to cause a multiplicity of complaints from the inhabitants of the districts adjoining the mines. Fortunately by that time an increased familiarity with the use of coal had improved our workmen in the method of applying it to smelting, so that the use of it for that purpose extended itself considerably after the middle of the last century.

Its surprising increase.

Seventy years ago our mechanics and hardware manufacturers chiefly made use of Swedish iron, and the quantity of English iron prepared did not exceed 20,000 tons a year: it soon, however, experienced a great increase, for our furnaces had were so increased that the iron made at them amounted

in 1788 to 68,000 tons,
1796 to 125,000
1806 to 250,000
1820 to 400,000
while at present (1832) it
is computed at nearly . 700,000

This vast quantity is made in the following parts of the Country:

Scotland, chiefly at the Carron works	40,000 tons.
Yorkshire and Derbyshire	65,000
Shropshire	80,000
North Wales	25,000
Glamorganshire and Monmouthshire	270,000
Staffordshire	220,000

Decline in price.

It thus appears that the quantity of iron annually made in this Country has tripled in the course of twenty years. This increase has, perhaps, been too rapid, for the present prices are not sufficient to indemnify the iron masters, or to enable them to pay sufficient wages to their workmen. A partial reduction of the number of furnaces has consequently taken place, but notwithstanding the present depression, no branch of our productive industry is more likely to recover, for none rests on more solid foundations. All our iron mines are situated in the vicinity of coal, and most of them have the advantage of a direct import of provisions from Ireland; in other words they are in the neighbourhood of cheap materials and cheap labour. In the transport of so heavy an article as iron, canals and railways are of first-rate importance, giving our iron-works an advantage not possessed by one in ten of those on the Continent. It may fairly be assumed that of no article is the use more likely to extend as Society augments its numbers, or improves its habits and institutions. In England iron is in progress of substitution for timber in various respects; abroad there must ere long be an end, particularly in France, to that impolitic system of high duties on English iron which go far to deprive the French Public of a most useful material. Add to this the probability, in this Age of invention and discovery, of further improvements in the mode of smelting, or otherwise preparing iron; comparatively recent as the manufacture is in this Country, and unfettered as it is likely to remain in respect to duty or excise regulations, which have so often proved an obstacle to useful experiments and amended processes.

Of the total of the iron annually made in this Country about a sixth part, or one hundred and twenty thousand tons, are exported; and the cheapness of freight in time of Peace is in favour of an increase of our exports.

Pig iron and wrought iron explained.

The name of cast or pig iron is given to the metal when first extracted from the ore: wrought or soft iron is pig iron refined, or rendered malleable. This process takes place in more than two-thirds of the iron annually made, after which it is formed into bars, bolts, rods, &c. for sale. The exports take place chiefly in wrought iron, because it is fit for immediate use by the

Mechanic, but the prices stated at the iron-works, or in the public papers, apply to pig iron. In years of brisk trade, such as 1824 and 1825, these prices were so high as £10 or £12 a ton; at present they are not half so much; so that vast as is the quantity (700,000 tons) made annually, the value does not exceed £4,000,000, to which £1,000,000 or £1,500,000 may be added for the cost of forming pig into wrought iron.

Hardware.

Such is the value of the whole of the iron or raw material prepared annually in Great Britain; but the hardware, or articles manufactured from iron, amount, in consequence of the labour bestowed on them, to nearly twice that sum. These articles are very various in their kind, and are made in surprising quantities: they comprise knives, scissors, razors, and all kinds of cutlery; fire-arms, swords, sabres, locks, bolts, bars, &c. In addition, hardware comprises a variety of articles made of tin, brass, copper, steel; in short, the almost endless list of goods which afford employment to the inhabitants of Birmingham, Sheffield, and the populous towns in their vicinity. In hardware, as in cotton, there has been, since the Peace, a very great increase in quantity accompanied by a heavy and general decline in price. As to the value of the iron and hardware of all kinds made in Great Britain at present, (1832,) the computed amount is £17,000,000 sterling, of which about £4,000,000, nearly a fourth part, is sent abroad. The chief foreign markets are the United States of America, Canada, India, and the West Indies.

Though this, like other branches of manufacture, has been for some time in a very depressed state, there is, happily, the strongest reason to anticipate a revival of its prosperity. The abundance of our coal and the cheap rate at which both it and iron are conveyed by canals, are of the greatest importance to this branch of our industry, and have, indeed, been the chief causes of its extension. To these are now to be added the advantages arising from the division and subdivision of employment in towns of so great extent as Birmingham and Sheffield, where the capital vested in trade is ample, and the machinery and tools used by the manufacturers are greatly superior to those of the Continent. In no other Country can hardware articles of equal quality be supplied at so cheap a rate. We are therefore justified in expecting a great eventual increase in the sale of our iron and hardware both at home and abroad. At home, iron is likely to be used more and more in public works, such as railways, or in roofs, pillars, beams, canal boats, as a substitute for timber. Abroad, particularly in France, the use of iron and hardware articles cannot fail to receive a great extension as soon as a reduction takes place, in the exorbitant and impolitic import duties. Those duties were intended to protect the iron-works of France, but the attempt is found to be unavailing; most of those works labouring, from insufficiency of fuel, under so serious a disadvantage that the Government of France would act wisely in making a pecuniary sacrifice towards indemnifying the owners, rather than continue to deprive its subjects of the various advantages that would result from the cheapness of an article of such first-rate importance as iron.

The Leather Manufacture.

Leather.

This department of our productive industry is on a footing considerably different from that of our cotton or hardware. The chief consumption of it is at home, and the export is comparatively small, because in this manufacture we do not possess any marked advantage over our Continental rivals. First, as to the supply of the raw material; the number of cattle in Great Britain and Ireland, computed at present between six and seven millions, is a great addition to the number half a century ago, while the weight of the animals, and consequently the size and weight of their hides, has increased surprisingly; but in neither is the augmentation proportioned to the increase in the consumption of leather, which, like our population, has more than doubled since the year 1780. We are consequently obliged to import annually a large quantity of hides, partly from Lithuania and other Provinces of Russia, where cattle run wild in the forests, but more from Paraguay, where among the immense herds that range the uncultivated tracts, thousands and tens of thousands of cattle are killed merely for the sake of their hides. Unfortunately, the troubled politics of that and other parts of South America for many years past, have limited the supply of hides and have kept up the cost of leather so highly that of all our manufactures it has experienced the least decrease of price since the Peace. It has been a matter of complaint that the repeal of the leather tax should have produced hardly any abatement in the price of shoes; but we must not imagine that the repeal was unavailing, for it prevented the rise which would otherwise have followed our annually increasing consumption.

The vast quantity of hides supplied by the slaughter of cattle in London are tanned chiefly in Bermondsey in Southwark, the seat of the largest tanneries in the World. There are also very extensive similar establishments in Lancashire, Staffordshire, and other Counties, in which the towns are populous and the carriage of hides from one part to another is facilitated by canals. In the further process of the manufacture, we mean making the leather into harness, saddlery, boots, shoes, &c., which is almost altogether carried on by manual labour, little advantage is derived from our national superiority in fuel and machinery. In France, leather is considerably cheaper than in England, but both its quality and the workmanship of the different articles made from it, are decidedly inferior. The total quantity of leather tanned and otherwise prepared in England is about 25,000 tons; the number of persons employed in the various branches of the manufacture about 250,000; and the value of all the articles made is about £15,000,000 a year, of which shoes alone form the half or upwards.

Gloves.

The making of gloves was carried on with considerable profit during our Wars with France, but received a serious check from the suspension, in 1812, of our trade with the United States of America, which were the chief foreign market for the article. Unfortunately the depression has continued in a greater or less degree ever since: the Americans now make gloves for themselves and the French rival us in foreign markets. Still we bid fair to maintain a competition with them, the chief labour in this article (that of women) being almost as cheap in England as on the Continent. Worcester, Yeovil, Ludlow, and Woodstock are the chief seats of the glove manufacture.

Silk.

The circumstances of our silk manufacture are very different from those of our hardware. The whole of

Progress of this manufacture.

the raw material must be imported: our canals are of no importance in regard to an article so light in comparison with its value; and even the cheapness of our fuel is in this respect but a secondary advantage. How then has it happened that the silk manufacture gained a footing in England? It seems to have owed its introduction to the large profits expected from an article costly in itself and consequently used by the higher classes. It was begun in this Country before the year 1500, and attained a certain extent in the course of the XVIth Century, particularly in the reign of Elizabeth, when a number of Flemish workmen settled in England in consequence of the political disturbances in the Netherlands. A further stimulus was given to it a century after by the repeal, in France, of the Edict of Nantes, and the removal of a number of the manufacturers to England. Unfortunately our Government began at that time to listen to the doctrine of monopolists, considering it politic to subject foreign silks to a high duty, and eventually to prohibit them *in toto*. Italy was then the quarter for supplying us with silk, whether raw or organzine, or, as it is commonly called, thrown silk. But in the year 1719, a Mr. Lombe, afterwards Sir Thomas Lombe, having obtained models of silk mills from Italy, established one at Derby for the purpose of throwing silk. To perform this process in England was accounted at the time a great acquisition; but there is now little doubt that the silk manufacture would have succeeded better in this Country had we been content to leave things to their natural course, and to impose no restraint on the import of thrown silk, while the duty on the manufactured article ought not to have exceeded ten or fifteen per cent. With so moderate a duty there would have been very little inducement to run the risk of smuggling foreign silks: the competition would have been open, and Government would soon have been enabled to judge whether the manufacture could stand its ground in this Country without factitious aid. But the course pursued was very different; foreign silks were either burdened with a very high duty or prohibited; a strong temptation was thus afforded to smuggling; and the amount of foreign silks clandestinely imported was probably not below half a million sterling a year, which a century ago was a very large sum. Hence a succession of complaints on the part of the workmen in Spitalfields, one of the results of which was an Act of Parliament obliging the masters to pay them wages according to a fixed scale. This compulsory Act ended, as compulsion in Commercial affairs always does, by defeating its own object; the manufacturers, in self-defence, established silk-weaving in Provincial towns, (Manchester, Norwich, Leek, Macclesfield,) which were out of the reach of the Act; and the result of the competition was a reduction in the rate of wages in Spitalfields.

Rivalship of cotton.

However, notwithstanding complaints on the part both of the workmen and their employers, the silk manufacture was continued and increased in correspondence with our population, so that towards the year 1785 the value of the silk annually made in England was computed to be nearly £5,000,000. It then began to suffer from the rivalship of cotton, which every year became more formidable as mechanical improvements followed each other. In the course of years, cotton fabrics became almost as elegant and, beyond all comparison, cheaper than silk: no effort on the part of the East India Company to reduce the cost and increase the quantity of silk imported from Bengal, could balance the cheapness of cotton, and the ease with which, from the nature of its fibre, it admits of the application of machinery. The latter advantage it possesses in a remarkable degree over wool, flax, and silk; so that the mechanical improvements in the manufacture of those articles have, in general, been first tried and made to succeed in cotton.

The consequence of the rivalship of a manufacture improving so rapidly as that of cotton, has been a frequent depression of the silk trade, and a recurrence of complaints among the weavers, chiefly in Spitalfields, but occasionally also in Coventry, Macclesfield, and the other Provincial seats of this manufacture. At last, in 1825, Government adopted a new system; the prohibition of foreign silks was declared at an end, and their import was allowed on paying a duty of 30 per cent. *ad valorem*. The duty on foreign thrown silk was lowered from 14*s*. 7*d*. per pound to 5*s*. The reduced rates were accounted by Government sufficient to protect both our throwsters and weavers; and in order to afford them raw silk at a cheap rate, the duty on it was brought down to 3*d*. per pound.

This Act has now been in operation seven years, a period of severe trial to the silk trade as to all ornamental manufactures, in consequence of the reduced circumstances of the majority of the consumers. Complaints have continued on the part of our manufacturers, and a higher duty on foreign silks has been called for; but, on the other side of the question, reference has been made to the rapid increase of the manufacture. This fact is established by the increased import of the raw material, which in the course of ten years has doubled: it is further shown by the increase of our exports, which though not yet large, (£400,000,) are fully double their former amount. It has now become a general opinion, that in all qualities of silk, except fancy goods, our workmen are equal to those of France, while in several they are superior.

Extent of the manufacture.

The number of weavers and other persons, young and old, employed in the silk trade, is not accurately ascertained, but is computed to exceed 100,000 in the whole Kingdom. The value made annually, in an article so high priced, is large in proportion to the number of persons employed; not less probably than £10,000,000 sterling. Our chief export is to the United States of America.

So far from acceding to an increase of the existing duty on foreign silks, the advocates of free trade contend that it would be for the advantage of our manufacturers if it were lowered to 15 per cent., as smuggling would then cease. Be this as it may, the remarkable difference in the success of the cotton and silk manufactures in this Country seems to have originated in the following causes.

1. The silk manufacture was long confined to London, where provisions, fuel, and house rent are and have long been considerably higher than in Lancashire.

2. The French and Italians had, in a manner, preceded us in regard to silks, while the production and supply of cotton for manufacture became large only at a time when our disposable capital had become great, when the supply of coal was extended by canals, and our town population was rapidly on the increase. Foreigners could buy the raw material as cheaply as our Countrymen, but they were greatly inferior to us both in capital and machinery.

3. To these the advocates of free trade add the advantage of leaving a manufacture to its natural

course; the interfereace of Government, even for the purpose of protection, being found in most cases to be eventually injurious.

Lace and stockings. Connected with the silk manufacture are the lesser branches of lace and stockings. Lace is made in large quantities in the midland Counties, *viz*. Buckingham, Bedford, and Nottingham. It is a manufacture of old date, and formerly gave employment to very many persons, chiefly females, to the number, it is said, of nearly 200,000 in all. The quantity of lace made in England is at present greater than ever, but machinery has in various respects superseded manual labour. Since the General Peace in 1815, the price of lace of all kinds has fallen greatly, so that the wages of the women employed, as well as of the workmen engaged on the power and hand looms, are much lower than formerly. Our chief rivals in this manufacture are in Flanders, which has long been noted for the variety and quality of its lace, and still preserves a superiority in embroidery.

The stocking manufacture is carried on likewise in the inland Counties of Nottingham, Derby, and Leicester; the quantity made annually is now greater than ever, but in this branch also machinery has greatly superseded manual labour. The value of the cotton and silk stockings woven annually in England is not below £2,500,000.

Earthenware We come in the next place to manufactures of a more homely nature, but which are likely, in the course of time, to acquire great extension in this Country, in consequence of our local advantages. The cheapness of our fuel is a first-rate point in making both glass and earthenware; while the extent of our canals is of equal consequence in sending them to a market. Both advantages are enjoyed at Newcastle in regard to glass, and in Staffordshire (in the Pottery district) in respect to earthenware. In the latter district a population of above 60,000 persons is engaged in preparing for market as well the porcelain or finer qualities, as the cheap and bulky earthenware required for common use. The value of the whole made annually at the Potteries is computed at £1,500,000, and of that made at Worcester, Derby, and other parts, at between £700,000 and £800,000. The portion of the whole exported yearly is about £500,000. The United States of America are our principal foreign market, and next to them Brazil and the West Indies.

and glass. In the XIVth and XVth Centuries the making of white glass was, in a manner, confined to Venice, and the chief towns of Italy; while, from the expense attending its conveyance to England, its price was such as to confine its use to the Court, the Nobility, and a few affluent merchants. It was in the latter part of the reign of Elizabeth, somewhat more than two centuries ago, that the improving circumstances of our farmers, manufacturers, and middle ranks generally, enabled them to adopt the use of what was at that time considered a luxury: hence a motive for manufacturing glass at home, particularly in the vicinity of our coal mines. The French have long carried, and still carry on this manufacture with spirit, but with means inferior to ours, both as to fuel and conveyance by water. The total yearly value of the glass made in Great Britain is about £2,000,000; that of the exports £500,000.

Sugar refinery. Another manufacture in which our abundauce of fuel is of the greatest importance, is the refining of sugar; this is carried on to a great extent in England, as well for home-consumption as for export. The latter, however, has been subjected to repeated checks from the duties imposed on the import of our refined sugars at Hamburg, St. Petersburg, and other ports, in which the respective Governments have endeavoured to confine the manufacture to their own citizens or subjects. The Germans, our chief rivals in this branch, have the advantage of cheap labour and of workmen accustomed to the business: we, on the other hand, obtain raw sugar at a somewhat lower rate, and have, in most situations, a cheaper supply of fuel. Our refineries are chiefly in London, Bristol, Liverpool, and Newcastle: in London, Bristol, and Liverpool, the refiners are supplied with raw sugar landed on the spot; at Newcastle, the want of this advantage is compensated, and perhaps more than compensated, by the cheapness of fuel. But whether in London or the outports, the workmen employed in this exhausting manufacture are chiefly Germans. The value of the refined sugar annually exported from England is about £2,000,000, and the chief markets are Italy and Germany.

Soap. In the South of Europe, the climate being favourable to the growth of olives, olive-oil is so abundant as to be the raw material for the manufacture of soap; but in England and other Northern Countries recourse is had to inferior materials, *viz*. tallow, soda, and potash. The quantity of soap made annually in England is between 50,000 and 60,000 tons, the value of which is about £1,500,000, or, after adding a very heavy excise duty, (3*d*. a pound,) £3,000,000. The latter is, of course, the sum paid by the Public for an article on which the duty ought to be moderate, as well from its being indispensable to cleanliness, as from the smuggling to which the high impost has given rise.

Hats. The total value of the hats made annually in Great Britain is between £2,000,000 and £3 000,000 sterling: the materials are the fur of the beaver for the finer hats, and wool for the coarser, or, as they are commonly called, felt hats. Having no superiority over neighbouring Countries, either in the purchase of these articles, or in the process of the manufacture, we do not export hats to the Continent of Europe: our foreign markets are confined to our colonies and Brazil, and the amount sent abroad not being above £200,000 annually, nine-tenths of the hats made in England are consumed at home.

The Brewery and distillery. We pass now to objects of a very different nature—to the produce of our breweries and distilleries. There are eleven Porter Breweries in London, which collectively brew about two millions of barrels of porter annually. The higher wages of labour in London and the higher price of fuel, have led to competition in Provincial towns in various branches, but not in porter brewing, because those drawbacks are counterbalanced by the great advantage of a market on the spot, nine-tenths of the beer made being consumed in the Metropolis and its vicinity.

In regard to a different liquor, spirits distilled from corn, the advantage of a market on the spot is of less importance, the freight from a distant port being a less serious charge on an article which is of considerable value for its bulk. The London distillers must therefore reckon on a continual competition with Scotland and the North of Ireland, notwithstanding the advantage to London of the late reduction in the coal-duty.

Malt has been subjected to an excise duty in England above a century and a half, and if the returns of the

Public Offices be assumed as a fair criterion of the quantity of beer annually consumed, the result is that its increase has borne a very inadequate proportion to the increase of our population. Thus in the forty years between 1787 and 1827, our numbers increased between 70 and 80 per cent., while the quantity of beer sold hardly increased 30 per cent. The means of purchase on the part of the lower orders having augmented in the course of that period, to what are we to ascribe their limited consumption of beer? To two causes: the extended use of tea and coffee, and the unreasonable amount of the beer duty, which exceeded the prime cost of the article until so lately as 1830, when it was reduced. The quantity of barley made into malt in England has not during many years exceeded an average of 3,300,000 quarters; but now that the duties on both beer and spirits are so materially reduced, the quantity of barley made into malt is in a course of progressive increase. The motive for lowering the duty on beer was twofold: the relief of the lower orders, and the benefit of the agriculturists. In the case of spirits the ground of reduction was different; it was to check illicit distilling, which prevailed to a most pernicious extent in Ireland and Scotland. That effect it produced, and the consumption of the different parts of the United Kingdom is now understood to be almost wholly of duty-paid spirits. The yearly average may be stated thus:

Ireland,	9,000,000	gallons of home-made spirit.
Scotland	6,000,000	ditto.
England,	8,000,000	ditto.

But of the quantity prepared in Scotland a considerable part is for the English market, in which there is also a consumption of rum and brandy far beyond that of the other proportions of the Empire.

Mineral Products.

Lead. Lead mines were wrought in Derbyshire before the XIIIth Century: at present they are worked not only in that County, but in Cumberland, Yorkshire, and Wales. The quantity formerly raised from our mines was above 20,000 tons annually, of which the half was exported. Of late years, however, the quantity of our exports has been much lessened by the rivalship of lead mines in the South of Spain, the ores of which are much more productive than those of this Country, and are wrought, of course, at less expense. The consequence has been a great decline in the price of lead; *viz.* from £23 to £14 per ton since the year 1820, so that many of the workmen in our mines have been obliged to emigrate.

Tin. In tin there is less dread of foreign competition, few Countries in Europe being possessed of tin mines: the chief rivalship in that respect is from a very distant quarter—the tin mines in the Island of Banca wrought by Chinese settlers. The produce of these mines is brought chiefly to Singapore, and is shipped in vessels which call at that port in their voyage homeward from China. The quantity of tin yearly prepared in England is between 4000 and 5000 tons, almost all in Cornwall; the average value is nearly £4 per hundred weight.

Copper. The copper mines of England are chiefly in Cornwall, and the quantity raised from them has been greatly increased during the last fifty years. Instead of 2000 or 3000 tons, the former produce, the quantity raised at present is 12,000 tons, of which more than one half is exported. The increase in the produce of our copper mines has been owing less to discoveries of ore than to the successful application of steam-engines to clearing the mines of water. Coal in Cornwall being brought from a distance, and consequently rather high-priced, it is necessary to study economy in its consumption; in other words to raise the water by pumping with as small a quantity of fuel as possible. Successive improvements have carried this economy of fuel to a great length; the shape of the boilers has been altered, and the air excluded with a degree of care unknown in Northumberland and Staffordshire, where coals are abundant and cheap. The consequence of this, and of the reduced cost of labour and materials, is, that our copper mines are at present in a prosperous state, although their produce is sold considerably below its former price.

Coal. The importance of our coal mines, great at all times, has increased surprisingly since the extension of our canals and the application of steam to mechanical purposes. An eminent French writer, aware how much we owe to this precious mineral, calls coal *cette vive force en lingots;* and a Writer of our own Country describes it as "hoarded power applicable to almost any purpose which human labour directed by ingenuity can accomplish." The quantity of coal consumed in London has been increased from time to time with the population of the Metropolis. It was in 1700 about 350,000 chaldrons; in 1750 about 500,000; in 1800 about 900,000; and at present (1832) about 1,600,000. The consumption for the whole Kingdom appears to be nearly 16,000,000 tons, including the large quantities used in manufactures, particularly in the making of iron, the smelting of copper and other metals.

The coal trade has long been one of the chief nurseries of our seamen. The number of men and boys employed in the coal trade between the Northern sea-ports and the Metropolis is about 15,000.

The export of coal was formerly subjected to a heavy duty, *viz.* seventeen shillings and sixpence per chaldron: this is now reduced to three shillings and fourpence, and safely may we increase our sales to foreigners, for the coal fields of this Country are so extensive as to afford a supply which at the present rate of consumption, would probably last more than a thousand years. Nor is it likely that the amount consumed in England will increase in proportion to our population, since there are various methods of economizing coal, of which we need only mention one of very easy application, that of heating buildings by steam.

The coal conveyed coastways, particularly to London, was long subject to a heavy duty, thus increasing greatly the cost of an article already enhanced by the charge of freight. This ill-judged and pernicious tax proved a drawback on the industry of all the Southern Counties: happily it is now repealed, as is an equally objectionable tax on coal brought by canals from Staffordshire and other inland Counties.

Salt. Salt, which in all Countries is of great importance for consumption, is in England valuable likewise as an article of export. It is obtained chiefly in Cheshire in the neighbourhood of Northwich, where there are vast quantities of rock salt in the mines, and of brine or salt-water in the springs. The rock salt when dug out is not sufficiently pure for use, but when mixed with the brine from the springs and refined in large iron pans, it is called white salt, and forms a great object of export from Liverpool to the United States of America. During the late wars with France salt was subjected to a very high duty; this was repealed in the year 1823, and although all the advantages anticipated from the repeal have not yet been realized, there seems little doubt that the Public will gain more by the unrestricted use of so valuable a commodity than by the produce of the tax, large as it was.

In the South of France, and in other warm Countries, salt is obtained by evaporating sea-water by the heat of the sun: the crystals of salt made in that way are accounted purer than the salt of the mines, in consequence of the comparative slowness of the process. A small quantity (8000 or 9000 tons) of sea-salt thus prepared is imported annually from Portugal into England. The quantity of English salt consumed in this Country is computed at 150,000 tons annually; but the quantity sent abroad is considerably greater. The chief foreign markets are the United States of America, British North America, Russia, Prussia, and the Netherlands. In each of these Countries it is less expensive to pay the freight of salt on vessels coming from Liverpool, than to pay the land carriage of salt from their own mines, or to evaporate it from sea-water at their respective ports; particularly in the Baltic, where the proportion of salt in sea-water is much less than in the Ocean.

The Shipping of England.

Its progressive increase.

The mercantile shipping of England was quite insignificant until the time of Henry VII.; it increased progressively during the reigns of that Prince and his successors of the Tudor and Stuart race, yet so slowly that at the Restoration, in 1660, it hardly amounted to 100,000 tons. In the period between 1660 and 1689 the increase was rapid, because our Navigation Laws had come into full operation, and during several years (from 1674 to 1679) our flag had all the benefit of neutrality, the Dutch, who were then the great monopolists of shipping business, being involved in war with France. In our subsequent contest with the latter Power (from 1689 to 1697) our mercantile tonnage was necessarily lessened, but during the ensuing interval of Peace it recovered, and was found in 1702 to amount to 270,000 tons, manned by 27,000 seamen. In the present Age of extended navigation it is curious to observe the slender returns made on that occasion from our principal sea-ports:

		Vessels.	Seamen.
In 1702,	London	560	10,000
	Bristol	165	2,400
	Hull	115	1,200
	Liverpool	102	1,100
	Exeter	120	1,000
	Yarmouth	143	700

The following Table exhibits the remarkable increase of our shipping during last Century.

***British** Shipping after 1702. **Tonnage of the Vessels** cleared outwards in various years.*

Years.	Tonnage.
1709	244,000
1715	421,000
1728	433,000
1738	476,000
1750	610,000
1765	726,000
1774	900,000
1785	1,075,000
1789	1,515,000
1802	1,627,000

As we draw nearer to the present time the returns of our mercantile navy are more complete.

***British** Shipping engaged in Foreign Trade (distinct from the Coasting Trade,) which entered inwards in the following Years.*

Years.	Tonnage.	Seamen.
1820	1,668,000	100,000
1824	1,797,000	109,000
1828	2,094,000	119,000
1829	2,184,000	122,000
1830	2,180,000	122,000

***Tonnage** of the Merchant Vessels belonging to our principal Seaports in 1829.*

	Tonnage.
London	573,000
Newcastle	202,000
Liverpool	162,000
Sunderland	108,000
Whitehaven	73,000
Hull	72,000
Bristol	50,000
Aberdeen	46,000
Yarmouth	41,000
Whitby	42,000
Glasgow	41,000
Greenock	36,000
Dundee	32,000
Scarborough	28,000
Leith	26,000
Plymouth	25,000
Belfast	25,000
Dublin	21,000
Dartmouth	21,000
Grangemouth (Scotland)	24,000
Beaumaris	22,000
Cork	17,000
All the lesser Ports	504,000
Total of the United Kingdom	2,200,000
British plantations	317,000
Seamen belonging to the mercantile shipping of Great Britain and Ireland in 1829	134,500
Seamen belonging to the British Plantations	20,000

Decline in the value of shipping.

No part of the mercantile community has suffered more severely since the Peace than the shipping interest, and in no branch of our industry is the competition of foreigners more to be dreaded than in ship-building. The cost of provisions being so much less abroad, the wages of shipwrights are comparatively low, while in some quarters, particularly in the ports of Norway and the Baltic, timber is much cheaper. Ship-building, in England, has consequently diminished; from 100,000 to 150,000 tons is the measurement now annually constructed; and that chiefly owing to our Navigation Laws, which, notwithstanding the relaxation of late years, require that British built vessels should still be exclusively employed in several important branches. This applies as well to the home trade as to the trade with our colonies, India, and China.

Ports for ship-build-

Our merchant vessels were formerly built in a great measure at Blackwall, Woolwich, and other yards on the Thames; hence the name of "river built;" but the lower wages of the Northern ports have long since attracted the chief part of this business to

Hull, Whitby,
Newcastle, Scarborough,
Sunderland, Whitehaven.

The vicinity of the New Forest to Southampton and of the Forest of Dean to Chepstow, led during the late War to establishments for ship-building at those ports, but they have as yet been attended with little advantage to the speculators. Nor does it seem likely that, in any part of the Kingdom, the distress of the ship-builders will be effectually relieved until the duty on Baltic timber shall be repealed or materially reduced. When a measure of that kind shall be adopted, the intelligence of our workmen, their better tools, and the greater capital of their employers, may enable us to maintain a competition with the ship-builders of the Baltic and the United States of America.

The mercantile shipping employed in our trade with Canada and our other North American

Colonies amounts to	400,000 tons.
With our West India Colonies	220,000
With the East Indies	100,000
With China	20,000

The number of vessels, generally small, employed in our coasting trade and in our intercourse with Ireland is about 3000; of which the half in tonnage, if not in number, belong to the coal trade.

The fisheries.

It has often been matter of surprise, that with such abundance of fish on our coasts, and such liberal encouragement from Government, our fisheries should not have attained a greater extension. The value of all the fish caught on our coasts and in our rivers does not exceed £2,500,000, not one-tenth part of the price of the butcher's meat annually consumed in England. This is to be ascribed, partly to the frequency and long duration of our Wars, partly to the inefficacy of systems of bounty in almost any form. Something also is to be attributed to the sale of fish in London having until lately been confined to one market. The removal of that abuse, joined to the additional capital and number of hands now employed in the fishery, will greatly increase the quantity of fish brought to the Metropolis and the inland towns. Accelerated conveyance by steam-boats and steam-carriages will operate to the same result. At times when, as in the year 1812, bread and butcher's meat were high-priced, the experiments made in forwarding fish to inland districts were highly encouraging; large quantities, slightly corned, having been sent from the coast to the interior at a charge almost too inconsiderable to be named.

The Newfoundland fishery has long been conducted on an extensive scale, and employs about 6000 seamen. But the herring fishery on our coasts has been the chief object of bounty on the part of Government, for the double purpose of enabling our Countrymen to compete with the Dutch, and to render the fishery a nursery for seamen. Many years ago a bounty was given on the busses or vessels employed in this fishery: subsequently, in 1808, the bounty was extended, and was paid partly on the tonnage employed, partly on the quantity of fish caught and cured. After the general Peace of 1815, the form of the bounty was further altered, and was awarded solely in proportion to the quantity caught. Of late years, however, the rule of withdrawing all artificial encouragement has been applied to this branch of our industry; the bounty has totally ceased since 1830, and it is considered that in this, as in the case of silk, the capital and labour employed will now be better rewarded than when the bounty was in operation. Men engaged in other employments, who used to go to sea during a few months in Summer for the sake of the bounty, are now withdrawing and leaving the business to fishermen, who make it their regular and almost constant occupation.

Summary of our Imports and Exports.

Our imports distinguished by the respective Countries.

The chief articles of import from other Countries into England are the following.

From Ireland; linens, oats, wheat, cattle, pigs, salted provisions and butter, the whole forming an amount of £6,000,000 or £7,000,000 annually.

From the Baltic, *viz.* Russia, Poland, Prussia, Sweden; timber, pitch, tallow, iron, wheat, hemp, flax, pot-ash.

From Holland; oats, wheat, seeds, cheese, butter, also gin.

From France; wine, brandy, silk, lace.

From Germany; corn, wool, flax, linen, also timber and Rhenish wine.

From Spain and Portugal; wine, brandy, oil, fruit.

From Italy and the Levant; silk, oil, fruit, and drugs.

From Egypt; cotton.

From the United States of America; cotton, tobacco, rice, and flour.

From South America; cotton, hides, indigo, cochineal.

From the West Indies; sugar, rum, coffee, cotton, pimento.

From the East Indies; indigo, silk, cotton, sugar, spiceries, and occasionally rice.

From China; tea, silk, nankeens, tin.

From Canada, Nova Scotia, New Brunswick, Newfoundland; furs, skins, timber, fish, and seal-skins.

Exports.

Such are our principal articles of import. Our exports consist of cottons and hardware to almost all the Countries mentioned above; of woollens, linens, earthenware, to most of these Countries: and to a smaller number, of refined sugar, coffee, indigo, glass, machinery, coals, fish, to which are to be added articles of a very different nature, *viz.* silk, stationery, hats; all, or almost all, being manufactures, while our imports are generally of raw produce.

Next, as to the amount in money of our imports and exports.

Value of our annual Imports from and Exports to Foreign Countries; being an average of several years, but having reference more particularly to the year 1829.

	Imports from	Exports to
Russia	£4,000,000	£3,000,000
Sweden and Norway	250,000	300,000
Denmark	480,000	250,000
Prussia	1,300,000	800,000
Germany	2,000,000	10,000,000
Netherlands	2,000,000	5,000,000
France	2,000,000	1,000,000
Portugal and Madeira	400,000	2,000,000
Spain	1,000,000	3,000,000
Italy	800,000	4,000,000
Turkey and Greece	500,000	1,500,000

	Imports from		Exports to
Egypt	£250,000	..	£130,000
Cape of Good Hope	250,000	..	380,000
West Coast of Africa	250,000	..	500,000
Mauritius	500,000	..	300,000
New South Wales	120,000	..	300,000
British North America	900,000	..	2,000,000
West Indies	8,000,000	..	5,000,000
United States of America	6,000,000	..	6,000,000
Mexico and Columbia, (exclusive of silver)	250,000	..	1,000,000
Buenos Ayres	500,000	..	1,300,000
Brazil	1,500,000	..	4,000,000

Mode of liquidating balances.

With some Countries, such as the United States of America, the amount in money of our imports and exports is nearly equal: with others, such as Germany, Spain, and France, the difference is great; to a degree, indeed, which makes it at first difficult to understand in what manner the balances are liquidated. The means of doing so are partly by the transmission of specie, but more by bills of exchange drawn by the merchants of one Country on those of another, for example, from Brazil on Portugal. These, when remitted to London, form a fund for paying to our merchants a part of the balances annually due to them by Brazil. The *bourses*, or mercantile exchanges of London, Amsterdam, Paris, Hamburgh, and, in a lesser degree, those of Lisbon, Cadiz, Frankfort, are the central points for such negotiations for the sale and purchase of the bills, by means of which the debts of one nation to another are liquidated with comparatively little transfer of coin or bullion. This arrangement may be compared to the manner in which the London bankers discharge their daily balances with each other by an exchange of cheques, without requiring any large sum in Bank notes. So far do the bankers carry this economy of money, that balances amounting to £4,000,000 may be, and generally are liquidated without using more than £200,000 in notes.

Low valuation of imports.

It is fit to add that the mode of valuing the imports in the preceding Table is different from that of valuing the exports. The latter are estimated at the market price, agreeably to the sums declared by the exporting merchants; the former by an official scale established so long since as 1696, when the prices of most of the articles we import were lower than at present. Were our imports rated at the current or market price, the sums would be considerably larger, and there would consequently be a greater approach to equality in the value of our imports and exports. We subjoin a Table of the

Value of our Exports classed, not by the Countries to which they are sent, but by the respective articles.

Cotton cloth	£13,000,000
Cotton yarn	2,000,000
Woollens	5,000,000
Linen (chiefly Irish)	2,000,000
Iron and steel	1,300,000
Hardware and cutlery	1,400,000
Brass and copper articles	700,000
Lead and shot	180,000
Tin, wrought and unwrought	350,000
Machinery and mill work	300,000
Silks	400,000
Haberdashery and millinery	500,000
Earthenware	500,000
Glass	500,000
Leather, *viz.* shoes, saddlery, harness	£350,000
Sugar, chiefly refined	2,000,000
Soap and candles	270,000
Hats	200,000
Salt	300,000
Beef and pork salted	150,000
Fish	300,000
Coals	400,000
Beer and ale	300,000
All lesser articles, whether of produce or manufacture	5,000,000

The above is the value as declared by the shipping merchants, and applies to the years 1830 and 1831.

Trade of England compared with that of the United States of America.

The preceding statements may receive some illustration by a comparison of the trade of this Country with that of our Transatlantic brethren. While the imports into England consist chiefly of raw produce, or the materials of manufacture, such as cotton, wool, timber, and our exports are almost wholly of manufactures,—in the United States, the reverse holds in both respects. There, the imports consist of manufactured goods, the exports of raw produce. The causes in either case are obvious; England has an abundant population with a limited territory; while in America, the population is still thinly spread, and the territorial surface is almost boundless.

The Tariff of 1828.

It has been the practice of almost every Government in Europe to study an indiscriminate extension of manufactures without much attention to the limitations rendered proper by the nature of their respective territories; hence the endless prohibitions and high duties on foreign articles under the mercantile system. To that system a number of our merchants and some of our public men are still attached, and the Americans, much as they have professed to admire freedom in trade, have given an unfortunate proof of the contrary by the Tariff enacted in 1828, which burdens all foreign manufactures with heavy duties. By what means was an act so contrary to the general rules of the American Government passed into a law? By the influence of the manufacturers; for the Tariff is an attempt to confine to that interest the supply of manufactures of almost every kind consumed in the States; in particular cottons and woollens. This Tariff has already been the source of much division between the different States of the Union; it has of late been somewhat modified, but cannot fail, if persisted in, to lead to very serious discontents. The extent of evil arising from it has not yet been fully developed, but it will, we may be assured, be as great as that which this Country has so long suffered from the imprudent interference of Government in former Ages with the natural course of trade.

Manufactures unsuited to the United States.

The chief obstacles to manufacturing industry in America are the high price of labour, the want of good roads, and the remoteness of the towns from each other. Ages must pass before these drawbacks can be removed, and at present it would evidently be more advisable to direct the surplus capital and labour of the Country to the culture of the soil. The chief products of the United States, wheat, cotton, tobacco, rice, have all, it is true, fallen greatly in price since the Peace; yet that ought not to discourage the cultivation of articles for which the market is so extensive, embracing, as it does, the West Indies, South America, England, and several Countries in Europe.

The situation of England in respect to manufactures is quite different from that of the United States; we possess remarkable advantages in

Advantages of England as a manufacturing Country.

1. The cheapness of fuel, and the consequent facility of applying steam to machinery.

2. In case of communication, whether by sea, by canals, or by roads.

3. In the cheapness of iron, and a decided superiority in all machinery and tools made of iron.

These are physical advantages; but to them we may add others of a different kind almost equally important, *viz.*

The lower rate of interest consequent on the magnitude of our disposable capital; and

The division and subdivision of employment, particularly since the population of our towns has received so great an increase in the present Age.

Our disadvantages.

On the other hand, we are subject to several drawbacks; they are as follows:

1. The price of provisions, which, though greatly reduced, are still from 10 to 15 per cent. above the rate of our foreign rivals.

2. The pressure of taxation, or rather of particular taxes, such as that on timber, which cramps our intercourse with the Baltic, and that on sugar, the amount of which is so great as almost to ruin our West India planters.

3. In high charges resulting from the War and a depreciated currency. In the case of articles sold in open market, such as corn and manufactures, the war charges have fallen long since; but they still exist in an oppressive form in other cases, such as the rent of land let on lease, in the rent of houses, in professional fees, and in various other demands, in which our laws and usages are such as hardly to allow of a direct or speedy reduction.

Computed profit from our manufactures and trade.

After these ample details of our commercial industry, it would be desirable to convey an estimate of the annual profit attendant on undertakings so vast. No attempt was made to calculate such profit until the imposition of the Property-tax in the beginning of this century, when, among the other returns to the treasury, there appeared one of the collective income of our merchants and manufacturers. Mr. Pitt forming, as persons not engaged in trade are generally inclined to do, a high estimate of its profits, had computed the probable amount of mercantile income in Great Britain at forty millions annually; but the returns made under the Act proved considerably less, having in no year exceeded thirty millions. There were, no doubt, many cases in which mercantile men declared less than their real income; but, on the other hand, there were not wanting examples of their continuing to return the usual amount of income in years in which they had sustained heavy losses; their apprehension being that a diminished return might affect their credit.

What, it may be asked, is the probable amount of the income of our merchants and manufacturers at present, compared to its amount during the War? The number of persons employed in Commerce is, doubtless, far greater at present, but there is, and has long been, a general complaint of insufficient profit, even in the branches which have received the greatest extension, such as cotton and hardware. The causes of this are sufficiently clear; during the War, the keenness of competition was greatly lessened by the demands of Government; the public service attracted annually many thousands of our population and many millions of our capital; hence a continued rise in prices as well as in the wages and incomes of all ranks. But since the Peace, capital, intelligence, labour, have all returned to their natural channels and been directed to the increase of products. This, added to the changes in the currency, has caused a great and general fall in prices, wages, and incomes; and although the number of persons employed in this Country in trade and manufactures is greater by fully 30 or 40 per cent. than it was twenty years ago, it is very questionable whether the income of this augmented number, if returned in money, would be at all equal to that of the same classes during the War. We say, "if returned in money," because there can be little doubt that in the power of purchasing goods, the present income of our merchants and manufacturers is considerably greater than during the War in consequence of the comparative cheapness of commodities.

Fluctuations in the currency.

This leads to the consideration of the greatest of all the changes that have taken place in the state of Commerce during the present Age—the change in the value of gold and silver. During twenty years (from 1793 to 1813) prices were progressively on the rise, and during a period nearly as long, they have been, with very few intervals, on the decline. Many persons ascribe this decline to the reduced supply of gold and silver, the mines of America, formerly so productive, having, during the last twenty years, yielded less than half their usual amount. Whatever be the cause, the extent of loss from declining prices is enormous; nor can any one say with confidence how the evil is to end. The deficiency in the produce of the American mines continues year after year, and the present management of them, whether by the native owners or the English Companies, is much less successful than that which was followed in the time of the Spanish Government. We have seen in a preceding part of this Essay (p. 90, 91.) how greatly the influx of gold and silver from America extended the trade of Europe in the XVIth and XVIIth Centuries; and it is a matter of the greatest interest to ascertain how far it may be possible to lessen the pressure at present so severely felt from their diminished supply. To arrive at a decided opinion on this subject, it is requisite to go back to an early period in the production of the precious metals, a subject closely connected with the History of Commerce, and on which considerable light has been thrown by a late publication of Mr. Jacob, of the Board of Trade, already known to the Public by his Reports on the Agriculture of Germany and Poland. Mr. Jacob's book discovers extensive research, and exhibits in connection a great deal of information which had previously existed in a very scattered state.

The Precious Metals; Historical Sketch of their Production, and of their Influence on Commerce.

Circulated at first by weight.

Gold and silver appear to have been in estimation at an early period in every Country of which we possess records. This was a natural consequence of the beauty and durability of these metals: valued at first as ornaments, their use as a circulating medium began subsequently, and for many years after it did begin, they were paid and received by weight, and not in the form of coin, for coin requires an established Government, as well as an improved state of Society. Abraham, the earliest Patriarch of whom we have a circumstantial history, and who lived about nineteen centuries before the Christian Era, is described in Scripture as rich in those metals, and as paying for his purchases in silver, not in coin but by weight, "according to the currency of the merchant." Gold was too scarce and too valuable to form the circulating medium of that early Age: it was used almost wholly for ornament, like sapphires, pearls, rubies, and other jewels. In this manner it was applied by King Solomon in building the Temple at Jerusalem and the Royal Palace. "He overlaid," we are told in Scripture, "the oracle with gold; also the whole altar that was by the oracle, he overlaid with gold." We have already noticed (page 79.) the extension of the trade of Judæa at that epoch. The quantity of gold brought into the Royal coffers in the reign of Solomon appears to have been between £200,000 and £300,000 sterling a year; that of the silver brought in is not distinctly stated. At that time the only wealthy Countries were Assyria, Egypt, and Judæa, for Greece was then only in a primitive stage of civilization.

Egypt early civilized.

The public treasure in Jerusalem.

The early Annals of the Jews are of great interest to the student of Ancient History, as furnishing information not only of themselves, but of the Egyptians and Phœnicians, long before it could have been obtained from any other quarter. The earliest date of written records in Greece was later by five centuries than the time of Moses, and the promulgation of his laws in a written form. It appears from this and other facts in History, that the use of letters was known in Egypt much earlier than in Greece, for it was chiefly to the fortunate circumstance of Moses being educated at the Court of Pharaoh that he owed his superior attainments. "He was skilled," says the Scripture, "in all the learning of the Egyptians." The mines in Nubia and other parts, wrought for account of the Egyptian Government, had been so far productive as to replenish the public treasury, and afford to the industrious and prudent the means of laying up property in the portable form of gold and silver. By this the Israelites had profited; for it is apparent from Scripture, that on leaving Egypt, they carried with them a considerable stock of the precious metals. The additions made to this stock in their subsequent wars were generally lodged in the public treasury, and protected by the solemn sanction of Religion: all was kept in the Tabernacle under the title of "Treasure of Jehovah." It follows that the metallic wealth existing in so considerable an amount under Solomon, was the accumulation of successive Ages, and its extent is thus in no way inconsistent with his limited territory, or the still more limited property of his subjects. That politic Monarch married a daughter of the King of Egypt, and maintained a close alliance with Tyre, which was then at a high point of prosperity. There were happily no national jealousies to interfere with the cordiality of the two Countries: the Jews, amidst all their offensive wars, had had none with the Phœnicians, whose territory was fortunately at some distance from Judæa.

The Treasury of Persia.

After the reign of Solomon, there took place, as is well known, great disorders in the Jewish Government, but amidst all these, the public treasure, or a considerable part of it, appears to have been preserved, and to have been removed to Babylon after the conquest of Judæa by Nebuchadnezzar. In Babylon this and much other treasure, conveyed thither from conquered Provinces, fell into the hands of the Persians on the conquest of the Empire by Cyrus. His successor Cambyses added to it an ample store from the treasury of Egypt. Persia was now the principal Empire in the World, and its yearly revenue is understood to have amounted to three or four millions sterling. By this is meant the clear sum forwarded by the Satraps, or Provincial Governors to the Royal exchequer, after defraying all local charges. But of this large amount very little was put into the form of coin. "The gold and silver," says Herodotus, "were melted and poured into earthen vessels, and these, when filled, were removed, leaving the metal in a solid mass. When wanted for payments, a piece was broken off of the amount required for the occasion, and issued in the shape of coin." The gold coins of that Age are the earliest of any specimens known to exist: they were called, after the reigning Monarch, Darics, and were worth each about twenty-five shillings of our present money.

Of Athens.

The treasury of Athens could not, of course, enter at all into comparison with that of the Monarchs of Persia. It received from the petty Islands of the Archipelago, and other tributaries, a yearly revenue of £120,000 sterling, and the sum accumulated at Athens before the Peloponnesian war, was equal to about £1,200,000 sterling. That sum, so much greater than the contents of any other treasury in Greece, was one main cause of Athens being enabled, notwithstanding her heavy losses, to make head against Sparta and her confederates during nearly thirty years.

About a century after the brilliant era of Athens, the course of events led the Macedonian armies into the heart of Persia, and delivered the Royal treasures at Persepolis, Ecbatana, and other great cities, into the possession of Alexander. The amount of the whole is said to have been nearly £10,000,000 sterling, a sum far greater than had as yet been collected in any other Country, but not improbable when we consider that it continued to be the practice of the Persian Government not to coin and circulate their gold and silver, but to keep them stored.

Of Rome.

Passing in the next place to Italy and the Romans, we find that the extension of their dominion had the natural effect of bringing large amounts in gold and silver to the Capital from the Countries successively conquered. These came first into the hands of the military commanders and of the Civil governors of Provinces. The use of coined gold and silver had not even then become general, so that a considerable time elapsed ere these treasures were circulated among the Public. they remained a long time in the coffers of the State.

Mining for silver and other metals.

In Nubia.

We are next to advert to the means of obtaining regular supplies of silver and other metals; to the Art of mining. That Art could not, it is evident, have been carried on in ancient times in a manner at all similar to the systematic and refined form which it now bears in Germany and England. A rude Tribe could begin only by working the ore found near the surface: when that was consumed, the working was necessarily carried on under ground; a task of great difficulty, deficient as they were in those Ages in tools and machinery. Egypt appears to have taken a lead in mining as in other useful Arts. The mines wrought for account of its Government were situated at a great distance, being in Nubia about latitude 22° North, distant nearly a fortnight's journey from Assuan, the ancient Syene. The rude mode of mining practised there appears to have borne a considerable resemblance to that which is still followed in Spanish America: the ores were brought to the surface, not as in this Country in baskets drawn or hoisted up a shaft, but on the backs of workmen, a practice still common in Mexico and Peru. Again the ore, when ground to a powder, was thrown into a gentle current of water, in which the metallic or heavy particles sank to the bottom, and the lighter or earthy were carried away by the stream. A supply of mining labourers was kept up somewhat on the plan adopted by the Russians in

Siberia; by sending thither captives taken in war, convicts, and all political delinquents, with their families. The produce of these and other mines wrought for the Government of Egypt greatly exceeded that of any other mines in ancient times.

Gold obtained from the sand of rivers.

Such was in early Ages the mode of obtaining silver as well as copper and iron: gold, on the other hand, was procured by a more uncertain, but less laborious process; by washing the sand brought down by streams from mountain districts. This practice prevailed in various parts of the ancient World; in the Eastern Provinces of Persia; in that part of India (the North-West) which was subject to the Persians; and even in the remote region of Abyssinia, great part of which being mountainous, has streams which supply the materials of such a traffic. The Abyssinians appear to have conveyed their gold-dust by the Red Sea to Egypt and Phœnicia, thus furnishing to Thebes in Upper Egypt an additional source of wealth.

Mines in Greece.

The Greeks acquired the Art of mining from the Phœnicians, and carried it on first in the Islands, such as Crete, Thasus, Eubœa; afterwards on the mainland, particularly in Attica. The work was performed by slaves, who belonged to the proprietors of the mines, and were hired by the adventurers or lessees of the mines at a fixed rate. The latter supplied them with provisions and clothing, and added, at the end of the month, a small payment in money, equal, in power of purchase, to about thirty shillings of our currency. In the mountainous parts of Thrace there were silver mines which had been wrought for Ages, but which falling into the hands of Philip of Macedon, were rendered far more productive under his politic management, and yielded him a portion of the treasures which he employed with such fatal effect against the independence of Greece.

In Thrace.

In Italy.

Turning from Greece to Italy, we find the first accounts of mining relate to Etruria, into which the useful Arts had been early introduced from Greece, by a colony from Corinth. The Etrurians obtained from their mines, first copper, afterwards iron. The copper required by the Romans for coin in the days of their republican simplicity was during several centuries drawn from Etruria. Gold was obtained in small quantities in two parts of the North of Italy: in the North-West, in the Province of Aosta, by washing the sands of the Po; and in the North-East of Italy, in the country round Aquileia, as well as in certain parts of Illyria.

In Spain.

Spain being one of the most mountainous Countries in Europe, and visited at an early epoch by the Phœnicians and Carthaginians, it was to be expected that its metallic treasures would be turned to account. Gades, or Cadiz, was one of the earliest settlements of the Phœnicians; Seville, Malaga, Carthagena, followed some time after; and in a few generations a number of smaller towns were formed by settlers from the East, for the natives of Spain were quite in a state of barbarism. The population being, moreover, very thinly spread, it became necessary for the working of the mines to bring over labourers from Africa. The mines first wrought for Phœnician account were probably situated along the base of the Sierra Morena, near the Guadalquiver, by which their produce would be conveyed first to Seville, afterwards to the sea. In that quarter (at Guadal canal, in the Province of Cordova) was the silver mine of Bebulo, from which Hannibal is said to have stored his military chest before crossing the Alps, and striking such disastrous blows at the power of Rome.

Mining under the Romans.

The Romans possessed no silver mines until the progress of their arms, in the first and second wars with Carthage, led to their occupying the mines of their adversaries in Sardinia, Sicily, and the South of Spain. They soon after obtained possession of the mines of Macedon, and at a subsequent date of those of Persia and Nubia. In ancient times nine-tenths of the manual labour done was performed by slaves; or, to speak more correctly, the lower orders employed in country work, in mining, or in almost any kind of labour, were paid more by maintenance than by money. The practice of paying the labourer in money, and leaving it to him to provide for himself and family, was then but partially followed; still less was it the rule to apportion the remuneration of mining workmen according to the produce of the ores they raised. The latter is the only effectual means of checking the expense of mining, and as a Public Body is ill fitted to enforce the economy requisite in fresh undertakings, the Roman Government allowed the mines of the State to be gradually abandoned; so that after the Vth Century there seems to have been, in a manner, an end to mining for the public account. For account of individuals, mining was still carried on in certain parts, but we are now arrived at the Dark Ages, when there is a failure of records of various kinds, and of none more than of those relating to the precious metals. One thing admits of little doubt, *viz.* that from the reduced supply of gold and silver, there was a gradual reduction in the money prices of commodities in the latter Ages of the Empire; that is, an ounce of silver or gold then went farther in the purchase of commodities than in the flourishing times of Rome—in the days of Augustus and of Trajan.

Gold and silver scarce in the Middle Ages.

Price of cattle in England in the Middle Ages.

The laws passed from time to time by the Anglo-Saxon Princes prescribe the prices of certain commodities. Thus, those enacted about the year 1000 fixed the value of a horse at a price that would make 35*s.* of present money, that of a mare or colt at 23*s.*, of an ox or cow at only 7*s.* Cattle were then of very diminutive size, much inferior to those of later times; but the price prescribed for an ox or cow is so low as to be accounted for only by the uncultivated state of the Country; by tillage being limited to particular spots, while four-fifths of the land were forest or waste. Hence animal food was so cheap as to be an object in the market only after a bad season, when corn was scarce and dear: at other times the value of the animal in England was little more than the value of his hide, as is the case at present in the wilds of Russia and of Buenos Ayres.

Of wheat.

The price of wheat also in England during the Middle Ages is deserving of a few remarks. It is stated in several of our ancient records, but it did not form a fair criterion of the value of gold and silver for two reasons: first, wheat in those days was less the food of the lower, and even of the middle classes, than rye or barley; and, secondly, at a time when there were few storehouses for corn, little disposable capital to invest in it, and wretched roads to take it to market, the plenty in one part of the Country could not be made to relieve the scarcity in another. Hence the price of wheat differed greatly from year to year, and in separate districts. These facts are useful in estimating the value of silver in the Middle Ages. They tend to confirm the opinion of the late Arthur Young, that the average price of wheat in England during the XIIIth, XIVth, and XVth Centuries was not below a fifth of its present price, or 10*s.* a quarter. Labour, in like manner, was paid in those days with silver and copper in very small sums; but if to these we add the value of maintenance, which was almost always supplied to the labourer, we find that his remuneration was not so trifling as is commonly thought. Allowance also is to be made for the general inferiority of the workmen and of the articles sold in so rude an era, particularly manufactures, which with the exception of a few, such as woollens and leather, were nearly as dear as in subsequent periods of our History. The result seems to be that in the XIIIth, XIVth, and XVth Centuries in England, and as far as we know in Europe generally, the value of silver may be stated in the proportion of one to three, when compared with its present value: £100 in those days being equal, in the power of purchasing the various requisites of housekeeping, to £300 at present, and not to more.

The American mines.

We now come to a remarkable epoch in the production of the precious metals, the occupation of Mexico and Peru by the Spaniards. The supply of gold and silver obtained from the Western hemisphere during thirty years after its discovery, was wholly insignificant. Hispaniola, the only important Country then occupied by the Spaniards, was quite unimportant as a seat of mines. But in the year 1521, Cortez invaded Mexico, and occupied the Capital, together with most of the inhabited districts. After this event, the supply of silver from America to Europe increased to half a million sterling a year; an amount trifling according to our present ideas, but by no means so in an Age when so small a portion of the Public could afford to use silver plate, and when, consequently, almost all the silver that was imported was added to the money in circulation. In the course of thirty years, the effect on prices in England, from this and other causes, was very remarkable. "My father," said Bishop Latimer, when preaching in 1548 before his young Sovereign Edward VI., "my father rented forty years ago a farm at six pounds a year. He kept hospitality for his neighbours; he gave alms to the poor; but he that now has the same farm pays fourteen pounds of yearly rent, and is consequently unable to do any thing for his Prince, his children, or the poor." Other causes, doubtless, had a share in this rise of rent; but it is remarkable, that about the time this Discourse was delivered, the discovery of the rich mine of Potosi in Peru took place, after which the import of silver from America to Europe proceeded in an augmented ratio; at the rate, it is calculated, of two millions sterling a year. To this chiefly is attributed the rise of prices which continued during almost the whole of the long reign of Elizabeth, towards the close of which most articles cost nearly twice as much as forty or fifty years before.

Produce of the American mines from 1660 to 1700.

The mines of Potosi yielded considerable produce during the early part of this Century, but fell off towards its close; new mines, however, were opened in Peru and in the vast inland tract between that Country and La Plata. But the chief increase was in Mexico, and from the mines now held by London Companies, but which from causes, which shall be explained forthwith, have as yet proved unprofitable in their hands.

From 1700 to 1810.

During the XVIIIth Century the produce of the American mines experienced a great increase, particularly in Mexico. Quicksilver had now become cheaper, and rude as was the method of extracting the silver from the ore, the abundance of the latter was such as to afford a large return. From Peru also the supply of silver was large, particularly from the mines of Pasco, the object of so unfortunate a speculation by a London Company in the year 1825. Adding to all these the gold obtained in Brazil, the result was that, during the XVIIIth Century, America yielded on an average precious metals to the amount of six or seven millions sterling a year.

Reduced produce since 1810.

The insurrection of 1810 in Mexico was followed by a Civil war, by the destruction of part of the machinery employed on the mines, and some time after by the abandonment of a number of mining establishments. The effect of these disorders has been to reduce an annual produce of seven millions of silver to half that quantity; and as the mines in Europe have merely kept up their very limited supply, the consequence has been a decrease in the amount of coin in circulation throughout the civilized World of more than sixty millions sterling in the last twenty years, or more than three millions on an average annually.

Its effect on the circulating medium.

This decrease has taken place as follows. The quantity of gold and silver required for plate, watches, and ornamental manufacture is very large; probably not less than to the value of six millions sterling yearly. To this is to be added a loss by the wear of coin, by shipwreck, and other accidental causes to the amount of one million annually. To India, China, and other parts of the East, the annual transmission of silver from America and Europe, though less great than formerly, still amounts to nearly two millions, making in all a demand on the mines of eight or nine millions each year. And as the average produce of the mines in the last twenty years has been only five millions, there has been an annual deficiency of three or four millions sterling.

Aggravated by the reduction of paper currency.

But the actual deficiency has been considerably more, for gold and silver have been required in large quantities by several Countries, particularly England and Austria, to replace the paper-money that has been called in. At the general Peace of 1815, Austria had in circulation about a hundred millions sterling of Government paper; but as it was greatly depreciated, the Government considered itself justified in requiring it to be exchanged for paper payable in cash on demand, giving of the latter twenty florins, or two pounds sterling, for every fifty florins, or five pounds of the former. This operation absorbed gold and silver to the amount probably of twenty millions sterling. In England the absorption of specie has been still greater; the necessity imposed on our Banks of paying in cash on demand, and the subsequent replacing of the small notes by sovereigns, must have required the appropriation of specie (chiefly gold) to the amount of nearly twenty-five millions sterling. Add to these for the further sums required in the United States of America, in Russia, and other parts of Europe, a computed amount of fifteen millions, and we shall have a total of sixty millions sterling in gold and silver required to replace Bank or Government paper. The deficiency in the supply from the mines being to the same amount, the total difference between 1810 and the present time is no less than one hundred and twenty millions sterling; that is if four hundred and twenty millions sterling formed the currency of the civilized World twenty years ago, that sum is now reduced to three hundred millions.

So great a decrease would have been quite ruinous to trade, had not this Country and Europe happily continued at peace; there are now no demands for the military chests of armies, and not much for hoarding by timid individuals. Improved means of conveyance now transport gold and silver in a very few days from one

Capital in Europe to another; from London to Paris; from Paris to Vienna; from Amsterdam to Hamburgh; from Hamburgh to Berlin. By these means a given sum, such as £100,000 in gold, is made to perform certain exchange operations which might have required twice or thrice the amount in time of War. And fortunate it is for the interests of Commerce that it should be so; for the great and general increase of population, and the equally great increase of commodities requiring an augmented supply of money to circulate them, would otherwise have greatly aggravated the distress arising from the diminished stock of the precious metals.

English Companies connected with Mexico.

It was in 1824 that several Associations or Companies were formed in London to put the mining works again in a state of activity. They obtained leases of the principal mines, provided large capitals, and sent out to Mexico agents, machinery, and mining workmen. The efforts of these Companies have as yet been unsuccessful, owing chiefly to the following causes:

1. The mines were dilapidated to a much greater degree than was expected, and required very expensive repairs.

2. There being no silver mines in England, the agents and workmen sent out were, and still are, unacquainted with the proper processes, particularly for separating the silver from the ore. They follow the rude practice of the Mexicans, with very little attention to the improved methods which have been in course of adoption in Germany during the last thirty or forty years.

3. Mining, like all undertakings of difficulty in Mexico, had been managed by natives of Spain, the Mexicans having neither the information nor the activity required for such enterprises. But the Civil war having ended in favour of the Mexicans, the Spaniards were obliged to leave the Country, which was thus deprived of their capital, and of what it could equally ill afford, their intelligence and habits of business.

In the absence of Spaniards, the English arriving at the mines had recourse to the natives, who being ignorant of Mechanics, Chemistry, and the principles of mining, proved most incompetent assistants. They had, in nine cases out of ten, no other object than to cause as much English capital as possible to circulate amongst them. Hence the absorption of the chief part of the funds of the Companies in a very few years.

Prospect of the Mexi-

Such have been the causes of the failure hitherto of the Mining Associations; but what, it may be asked, is the prospect for the future? First, the mines of Mexico are very numerous, those that are exhausted bearing but a small proportion to those that continue productive. The ore is abundant but not rich: hence the necessity of employing many thousand workmen. In fact, the great extent to which mining has been carried in Mexico, compared to Peru and other Provinces of Spanish America, has been owing to a very simple cause, the greater supply of labourers. In Peru the population is chiefly in valleys, while the mines are in mountains, the keen air of which is highly pernicious to the workmen from the plains; but in Mexico, a continued table-land, the temperature is nearly the same throughout. The labourers employed at the mines have consequently good health, and progressively increase their numbers, like the miners in Cornwall and in Saxony.

It thus appears that the arguments in favour of a prospective increased supply of silver, are

The abundance of ore in the mines;

The increasing number of mining workmen;

And, on the assumption of continued Peace, a further supply of capital from England to work the mines.

On the other side of the question are:

The unacquaintance of our miners with silver ore;

The general ignorance of the Mexicans, and

The very slow progress of the Companies in correcting the defects of their present system.

It is well known that in any Country, Joint Stock Companies succeed only when the agency of their servants is confined to a few plain objects, and when all that admits of being delegated, is transferred to individuals acting on their own account. Thus at most of the mines in Europe the practice is to sell the ores as soon as they are raised to the surface, leaving to individuals the nice and difficult task of reducing the ores, or separating the silver from the dross. But in Mexico that practice is by no means general; several of the mining districts are as yet too poor and too thinly peopled to supply persons qualified to reduce the ores; and there are considerable difficulties in bringing such persons from Europe and settling them at the mines.

It is thus almost impossible to calculate with confidence the future produce of the Mexican mines, but a large increase is certainly not to be expected at present. And it is a Historical fact of great importance, that at no period during the last two hundred years has the supply of silver from America had much effect in raising prices in Europe; it has done little more than keep them at the scale they attained in the XVIth Century. Although the influx of silver was regularly on the increase, the consumption of it extended in nearly an equal proportion. The causes are, that of the silver raised annually from mines, only a third part is converted into coin, while two-thirds are used for plate, and other purposes of ornament. The demand for silver thus increases with the population and wealth of the civilized World; these have advanced continually during the last two centuries, and at no period has there been a greater prospect of their further increase than at present.

It follows, therefore, that an augmented supply of silver would be readily absorbed by the demands of the civilized World; and that there is at present no prospect of any such increase as would cause a rise in the price of commodities.

Commercial Prospects of England.

Merchants strictly practical in their habits.

While few departments of industry have been followed in practice to so great an extent as Commerce, hardly any has been less an object of study in regard to its principles. The habits of merchants are strictly practical, and when they act by rule, even the most judicious among them are unconscious that they do so, because such rules exist only in the mind of the individual, being the result not of study or of the lessons of others, but of his personal experience during a number of years. Many merchants are remarked as well for intelligence and reflection, as for extensive information; but as that information is not reduced into a system, and is brought forth only in occasional conversation, it expires, in a great measure, with the possessor; so that new generations are left to acquire experience, like their predecessors, by length of time and practice in business. Readily do we admit that practice and intercourse are as indispensable in forming a merchant as a lawyer or physician, but they do not supersede instruction by principle any more in trade than in law or medicine. Like these professions, Commerce has its general rules; its precepts affirmative and negative. Supported by the former, the merchant will persevere in an occupation or a connection which temporary disappointments might otherwise make him abandon: deterred by the latter, he will avoid those tempting but fallacious undertakings in which his unthinking brethren are so ready to engage.

Errors from their deficient information.

The year 1825. Mexico.

Poverty of mining districts.

and of all thinly peopled Countries.

The most effectual mode of proof is by example, and if we look for a case of suffering on the part of our merchants, from their being merely practical men, we shall find it unfortunately too soon: we need go no further than seven or eight years back, when the trade of Mexico and the rest of Spanish America was opened to this Country. Aware that quantities of gold and silver had for many Ages been supplied by those Countries, our merchants considered them wealthy in other respects, and entitled to large credits, as well for the manufactures they bought from us, as for the money which their respective Governments proposed to borrow. Hence arose large exports of our merchandise, followed by extensive loans on the faith of South American funds, and equally extensive advances on the security of their mines. We will not dwell on the amount of the loss thus incurred; on the millions thus transferred from England to the Western Hemisphere: the point is to consider whether the mania would have been carried so far had our merchants had the benefit of instruction in the Principles of Commerce. In the course of such instruction one of the earliest lessons would have been, that Countries producing gold and silver are in general poor: that mines of those metals do not, any more than mines of coal, or iron, or copper, offer their treasures on easy terms, but must be wrought with great labour, and under careful superintendence. The expense of mining is in general such as to restrict the profit on it to the same limited scale as the profit on agriculture or manufactures. Another important lesson derived from studying the History of Commerce is, that thinly peopled Countries, like Spanish America, are invariably bare of capital, whatever be their advantages as to soil and climate. The reasons are obvious: capital is a plant of slow growth, the result of skill, labour, and perseverance; advantages to be found only in populous and long settled communities. Holland, with a marshy soil and an uninviting climate, has long proved a valuable customer for our manufactures, because the amount of her population and the advanced state of their productive industry, enable her to supply us in return either with valuable commodities or with money arising from the sale of such commodities. But a region like Spanish America, which, compared to England, has not on the same extent one inhabitant to twenty, can have no wealth arising from manufactures, and not much arising from Country products. Of all such products, whether the indigo, sugar, and cotton of a tropical climate, or the corn and wines of more temperate regions, the main constituent is labour, and labour can never be abundant where the population is scanty. Simple as are these truths, a knowledge of them on the part of our mercantile Countrymen in the unfortunate year 1825, would have been the means of saving many millions to England.

War with the North Americans in 1775; its causes.

Our next example of miscalculation as to Commerce shall be of quite a different nature, and taken from the conduct of our Government in the last Century. It is now sixty years since the origin of our differences with our North American Colonies which burst forth into open war in 1775, and ended, after a seven years' struggle, in their separation from the Mother Country. Those Colonies had long been bound by Acts of Parliament to take their manufactures from England, and to send all their exported produce, their tobacco, their flour, their timber, to this Country in the first instance; that we might purchase as much as was wanted for our use, and have a profit on the sale of the remainder to foreigners. These restrictions seemed to our Statesmen, as to our merchants, of great advantage to the Mother Country. The war with the Colonies was of long continuance, and many persons in England lamented it, but they did so chiefly on considerations of humanity. No speaker in Parliament, no practical merchant, came forward to maintain that we should be able to retain our trade with the Americans without the aid of monopoly, England being the only Country in Europe that could afford the long credit rendered necessary by their scanty capital. Peace came in 1783, and our Countrymen were prepared to resign a great part of this trade, when to their surprise they found it not only continue but increase. Could political feeling have decided the question the result would have been different. The national attachment of the Americans was to the French. They had fought together against us; they had a mutual jealousy of our naval power; they were eager to draw closer their connection by the ties of commercial intercourse; but all was unavailing. Then, as at present, France was bare of capital, and not rich in manufactures; she could supply America only with wines and silk; the other great articles of consumption, woollens, linen, cotton, hardware, continued to be drawn from England. The result has been, that from America separated, or, as she styled herself, independent, we have reaped much more advantage than from the same Country when subject to our colonial laws. How much blood and treasure would have been saved had our Statesmen and our merchants been earlier aware of this truth; and had they known that the chief subject for their consideration was merely whether our Colonists were sufficiently advanced in political science to conduct their own Government. If they were so, it was clearly for the mutual advantage of Countries so distant from each other, to separate, each confining itself to the administration of its own affairs.

Wars of the French Revolution: financial miscalculations.

But of all examples of error arising from deficient knowledge of the principles of trade, the most striking was afforded during our late Wars with France. Ministers, merchants, Members of Parliament, were all deceived by appearances; all joined in believing that the impoverishing effect of former Wars was completely belied by our situation, Commercial and Financial, during that long contest. Money seemed every year to increase in abundance; the country gentleman receiving augmented rents for his farms; the town landlord for his houses; the manufacturer a higher price for his woollens, his linens, his hardware; while the humble mechanic, and the still humbler country labourer, experienced a progressive increase in their wages. So general a rise in the scale of payments could, in the general opinion, proceed only from increased wealth, and that wealth must, according to the mercantile creed, be obtained at the expense of our neighbours. Of this we had an amusing example in the writings of the late Arthur Young. "The French Revolution," he said, "burst forth like a volcano, laying the industry, manufactures, and Commerce of France, and eventually those of the whole Continent, in the dust. Britain became the emporium of the World, and such a scene of wealth and prosperity filled every eye in this happy Country as the Sun before had never shone upon."

Such was the general opinion of our merchants, and as to the cause of any great change, practical men seldom go far for a solution; our navy was unresisted on the ocean, and our mercantile shipping had increased; hence a common belief that our augmented wealth arose from foreign trade. Even men the least connected with Government, had no distinct idea of the temporary nature of our prosperity or of the probability of a reaction. Not that we were without examples in History of such a reaction; for Sir William Temple, in his interesting account of the trade of Holland in the XVIIth Century, had described, in a manner equally clear and impressive, the general stagnation in mercantile affairs which followed the Peace of Westphalia. A similar fall of prices took place after the Peace of Utrecht in 1712, and, in some degree, after our Peace with France, Spain, and the United States of America, in 1783. But of these latter changes there was no clear or satisfactory record, and, unfortunately, before the close of the last War, we had lost in Pitt the only Minister familiar with such a transition, the only one who, during the excitement of the War, had warned his colleagues of the reaction to be apprehended at a Peace. Serious, indeed, has that reaction proved; in point of time it has lasted nearly twenty years, while as to degree, it has, in very many cases, amounted to half the income of whole classes of the community.

Causes of the decline of price

Yet, long as has been the period of suffering, the Public are not, even at present, agreed as to its causes. By some it is ascribed to the free-trade system and the competition of foreigners; by others, and a very numerous body, to the resumption of cash payments; while a third party attribute it mainly to the decreased produce of the silver mines of America during the last twenty years. Each of these causes has, doubtless, contributed to the fall of prices, but they are insufficient to account for so great and general a result: for this fall has taken place in France, Italy, Germany, Countries in which Banks are almost unknown, and where, consequently, there were no small notes to be called in. It must owing, therefore, to causes of very comprehensive operation, and what so likely to hold the first rank in the list as the change from general War to general Peace; a change which gave back so many millions of capital, and so many hundred thousand hands to productive employment; which renewed the intercourse between all Countries, substituting open and unrestricted trade for the barbarous anti-commercial edicts of Bonaparte. If, in proof of this, we select any particular class of Society, we shall find that the decline of prices since the Peace has borne a remarkable proportion, both in its nature and degree, to their rise during the War; those who profited most during the contest having, in general, been the most reduced since the Peace. This holds in regard to most of the productive classes, or those who earn their support chiefly by personal exertion, and the employment of a limited capital. Of this description are farmers, and the very numerous Body, who, whether agriculturists, traders, or professional men, carry on their business with borrowed money. All these classes find the payment of their rent, interest, and other fixed money charges, much more heavy since the fall in the price of the commodities in which they respectively deal; involving as it does a decrease in the wages, salaries, and professional fees, which form their respective incomes. But that is not all: a similar decline has taken place in the value of their fixed capital, such as stock in trade, machinery, or buildings. Cramped thus in their power of employing the lower orders, a number of the latter are thrown out of work. We hear, year after year, of a superabundance of country labourers, owing not to there being more labourers than are required to raise the requisite supply of provisions, for of late years we have imported corn largely, but to the reduced capital of our farmers, which prevents them from giving employment to those who want it.

From how many classes of the community do we hear similar complaints? From the manufacturers of woollens, cottons, linen, and more pointedly still from ship-builders, and the iron and hardware merchants. One important part of our national property, houses, long maintained a high rent in consequence chiefly of our increasing population; but of late that property also has fallen. How easily might we continue this painful catalogue, this enumeration of losses and embarrassments consequent on the lavish use of paper money during the War. How clearly could all this be traced to a deficient knowledge of the Principles of Commerce and finance; but we will not dwell on past errors: we will turn to a more cheering theme; to the prospect of surmounting our distress and the means by which it is to be attempted.

Prospect of relief: our resources increasing.

Amidst all these embarrassments and complaints, there is evidently no falling off in the productive powers of the Country. The quantity of our yearly crops, the extent of our manufactures, the amount of our mercantile shipping are all greater than at any former time, and all in a state of progressive increase. It follows, then, that the real wealth of the Country continues in an augmenting ratio; the pressure on us arises from the evils of transition; from unfortunate fluctuations in our currency; from the prices of very many articles, whether of produce or manufacture, having fallen in a greater degree than the charge of preparing and bringing them to market. Now such a disproportion cannot continue; if we are not able to foresee in what manner or after what lapse of time the equilibrium will be restored, we may safely assume that restored it will be, because the existing insufficiency of price is as contrary to fairness and justice, as its long continuance would be contrary to all experience.

Our agricultural produce.

First, as to our annual growth of corn and other country produce. During the War, considerable uneasiness was felt by the Public at the insufficiency of our crops and at our consequent dependence on foreigners. "Provisions," it was said, "will rise in price, and our manufacturers will go to cheaper Countries. The corn-exporting part of Europe may, it was added, again fall under the sway of a madman like Paul of Russia, or of a headstrong despot like Bonaparte; in times of scarcity the consequences might be most injurious." But from such an apprehension we are now almost wholly relieved: the quantity of our yearly produce is increased; agricultural improvements are extending in Ireland, in Canada, and on the shores of the Euxine; Countries too remote from each other to be controuled by any single power. Sixty years ago it was a common notion that the English raised as much produce, and prepared as

Ireland.

Our manufacturers not likely to go abroad.

much of manufactures as the limited extent of our territory admitted; and a French Political Economist, the father of the well-known Mirabeau, told his Countrymen in a printed Work: "You have been outstripped in the career of productive industry by the English, but do not apprehend that they will continue to take the lead, for they have advanced as far as it is possible for them to go." Yet, at that time our annual crops were not half their present amount; our mercantile tonnage not one-third; our export of manufactures not much above a fourth of the present quantity! So much for the accuracy of this foreigner: among ourselves, a well-known writer on population long since sounded the alarm at our increasing numbers; while one of his antagonists, writing twenty years ago, comforted us with the assurance that we might be tranquil until our average numbers should amount to three hundred persons on a square mile. To that limit we are now fast approaching, the census of 1831 exhibiting about two hundred and seventy persons in England to the square mile; yet our farmers supply the augmented number with provisions as easily as their fathers and grandfathers supplied half the number in a former Age. The truth is, that we are wholly unable to fix a limit to the productive powers of a Country; Ireland, the most densely peopled part of the United Kingdom, which at present supports eight millions of inhabitants, may, under an improved system of agriculture, so add to her produce, as, at no remote date, to support, perhaps, twice her present numbers, and to send to England twice or three times as much wheat and oats as at present. We may, therefore, safely dismiss the apprehension of our manufacturers taking up their residence in cheaper Countries: at present provisions are not dearer in England than on the Continent by so much as a fifth or twenty per cent.; and there is great reason to think that the difference will become progressively less.

Superiority of England, in roads, canals, coal, iron.

But whatever disadvantage our workmen may labour under in regard to provisions, is balanced, and more than balanced by the cheapness of the other constituents of manufacturing prosperity, such as coal, iron, roads, canals, railways. In coal we have an unquestioned superiority, both as to the quality of the mineral and the means of conveying it. Coal is found in various parts of the interior of Europe; in Poland, in Austria, in Spain; but how limited are the means of transporting it, and how long the time that must elapse ere those poor and thinly peopled Countries will be able to make the canals and railways required for that purpose! The same holds in regard to iron, our mines of which were hardly known forty years ago, when we were content to look to Sweden for the supply of an article, of which we now make above 600,000 tons annually. As to canals, it is now about seventy years since they began to be excavated in England; that is, since the intercourse between our chief towns became such as to defray a mode of transport which in the outset is very costly. Now, on the Continent of Europe, canal communication is extensive only in the Netherlands; in France, much as it has been spoken of, it is still on a very limited scale; while in Italy, Germany, Spain, the canals are absolutely insignificant. It follows that most of the improvements effected in this Country at so heavy an expense, remain to be made on the part of the nations attempting to rival us; and with how inferior means on their part as to capital and machinery!

In town population.

Equally inferior are their means as far as such depend on the distribution of their population; with them the majority of the inhabitants reside in the country; with us they reside in towns. Take the twelve principal towns of France, and compare the number of their inhabitants with that of the twelve principal towns of England and Scotland, and in the case of each of the places compared, the superiority of numbers will be found on our side. Again, take the whole town population of France, and extensive as that Country is, the aggregate of the inhabitants of her towns will not be found to equal in number the town population of Great Britain and Ireland. In England, so improved is our agriculture, so important are the advantages arising from farming capital, from better implements, from subdivision of work, that thirty-three persons in one hundred are sufficient to raise provisions for the community at large; while in France the labour of fully fifty persons in one hundred is required for that purpose. How great is the superiority of workmen collected in towns over a scattered peasantry! how steady their continuance at one kind of employment! how exact their execution! Their better wages enable them to consume much more of taxed commodities; hence the large revenue of Holland a century and half ago, at a time when in the rest of Europe the names of Excise and Customs were hardly known: hence at present the payment in this Country by duties on consumption of twice as much revenue as in France. To whatever part of Commercial History we look, whether to ancient or modern times, to Egypt, Phœnicia, Greece, Carthage; to Modern Italy, the Netherlands, or the Hanse Towns, we find increase of town population the cause and accompaniment of augmented wealth. Nor is there any reason to question that we shall keep up and increase our superiority in this respect. The difference of expense between town and country is less in England than on the Continent, because the extent of our communications both by sea and land facilitate the transport of corn, fuel, timber, and other bulky commodities, and cause an approach to equality in most parts of the Kingdom. The improvements now in progress in our turnpike roads and railways bid fair to lessen further the cost of provisions in towns, and greatly to augment the number of their inhabitants.

Internal regulations.

Enough has now been stated to show how little we have to apprehend from the competition of foreigners. In our internal regulations, our laws relating to trade, Banking, and taxes, so far as the latter affect trade, our present sufferings are caused in a considerable degree by mistaken Legislation; by abuses allowed to remain on the Statute book on little other ground but that of prescription. This, however, is not the place, nor indeed, if it were so, have we either room or inclination to enter upon the dangerous and difficult review by which this subject must be illustrated. It may suffice to express our hope, that a time has now arrived in which the narrowness of private opinion will be superseded by a more expansive general reasoning, and in which Mercantile interests will be regulated not by caprice, accident, or prejudice, but by the more sure and enlightened guidance of a study of THE PRINCIPLES OF COMMERCE.

POLITICAL ECONOMY.

Definition of the Science.

Definition of the Science.

We propose in the following Treatise to give an outline of the Science which treats of the nature, the production, and the distribution of wealth. To that Science we give the name of Political Economy. Our readers must be aware that that term has often been used in a much wider sense. The earlier writers who assumed the name of Political Economists avowedly treated not of wealth but of government. Mercier de la Riviere entitled his Work *The Natural and Essential Organization of Society*, and professed to propose an organization "which shall necessarily produce all the happiness that can be enjoyed on earth."[*] Sir James Steuart states, that "the principal object of the Science is to secure a certain fund of subsistence for all the inhabitants, to obviate every circumstance which may render it precarious, and to provide every thing necessary for supplying the wants of the society."[†] The modern continental writers have in general entered into an equally extensive inquiry. "Political Economy," says M. Storch, "is the Science of the natural laws which determine the prosperity of nations, that is to say, their wealth and their civilization."[‡] M. Sismondi considers "the physical welfare of man, so far as it can be the work of government, as the object of Political Economy."[§] "Political Economy," says M. Say, "is the economy of society; a Science combining the results of our observations on the nature and functions of the different parts of the social body."[||] The modern writers of the English school have in general professed to limit their attention to the theory of wealth; but some of the most eminent among them, after having expressed their intention to confine themselves within what appears to us to be their proper province, have invaded that of the general legislator or the statesman. Thus Mr. M'Culloch, after having defined Political Economy to be "the Science of the laws which regulate the production, accumulation, distribution, and consumption of those articles or products that are necessarily useful or agreeable to man, and possess exchangeable value;"[¶] or, "the Science of values;" adds, that "its object is to point out the means by which the industry of man may be rendered most productive of wealth, to ascertain the circumstances most favourable to its accumulation, the proportions in which it is divided, and the mode in which it may be most advantageously consumed."[**]

It is impossible to overstate the importance of these inquiries, and it is not easy to state their extent. They involve, as their general premises, the consideration of the whole theory of morals, of government, and of civil and criminal legislation; and, for their particular premises, a knowledge of all the facts which affect the social condition of every community whose conduct the Economist proposes to influence. We believe that such inquiries far exceed the bounds of any single Treatise, and indeed the powers of any single mind. We believe that by confining our own and the reader's attention to the nature, production, and distribution of wealth, we shall produce a more clear, and complete, and instructive work than if we allowed ourselves to wander into the more interesting and more important, but far less definite, fields by which the comparatively narrow path of Political Economy is surrounded. The questions, to what extent and under what circumstances the possession of wealth is, on the whole, beneficial or injurious to its possessor, or to the society of which he is a member? what distribution of wealth is most desirable in each different state of society? and what are the means by which any given Country can facilitate such a distribution?—all these are questions of great interest and difficulty, but no more form part of the Science of Political Economy, in the sense in which we use that term, than Navigation forms part of the Science of Astronomy. The principles supplied by Political Economy are indeed necessary elements in their solution, but they are not the only or even the most important elements. The writer who pursues such investigations is in fact engaged on the great Science of legislation; a Science which requires a knowledge of the general principles supplied by Political Economy, but differs from it essentially in its subject, its premises, and its conclusions. The subject of legislation is not wealth, but human welfare. Its premises are drawn from an infinite variety of phenomena, supported by evidence of every degree of strength, and authorizing conclusions deserving every degree of assent, from perfect confidence to bare suspicion. And its expounder is enabled, and even required, not merely to state certain general facts, but to urge the adoption or rejection of actual measures or trains of action.

Limits of the Science

On the other hand, the subject treated by the Political Economist, using that term in the limited sense in which we apply it, is not happiness, but wealth; his premises consist of a very few general propositions, the result of observation, or consciousness, and scarcely requiring proof, or even formal statement, which almost every man, as soon as he hears them, admits as familiar to his thoughts, or at least as included in his previous knowledge; and his inferences are nearly as general, and, if he has reasoned correctly, as certain, as his premises. Those which relate to the nature and the production of wealth are universally true; and though those which relate to the distribution of wealth are liable to be affected by the peculiar institutions of particular Countries, in the cases for instance of slavery, legal monopolies, or poor laws, the natural state of things can be laid down as the general rule, and the anomalies produced by particular disturbing causes can be afterwards accounted for. But his conclusions, whatever be their generality and their truth, do not authorize him in adding a single syllable of advice. That privilege belongs to the writer or the statesman who has considered all the causes which may promote or impede the general welfare of those whom he addresses, not to the theorist who has considered only one, though among the most important, of those causes. The business of a Political Economist is neither to recommend nor to dissuade, but to state general principles, which it is fatal to neglect, but neither advisable, nor perhaps practicable, to use as the sole, or even the principal, guides in the actual conduct of affairs. In the mean time the duty of each individual writer is clear. Employed as he is upon a Science in which error, or even ignorance, may be productive of such intense and such extensive mischief, he is bound, like a juryman, to give deliverance true according to the evidence, and to allow neither sympathy with indigence, nor disgust at profusion or at avarice—neither reverence for existing institutions, nor detestation of existing abuses—neither love of popularity, nor of paradox, nor of system, to deter him from stating what he believes to be the facts, or from drawing from those facts what appear to him to be the legitimate conclusions. To decide in each case how far those conclusions are to be acted upon belongs to the art of government, an art to which Political Economy is only one of many subservient Sciences; which involves the consideration of motives, of which the desire for wealth is only one among many, and aims at objects to which the possession of wealth is only a subordinate means.

[**] *Ibid.* p. 8

The confounding Political Economy with the Sciences and Arts to which it is subservient has been one of the principal obstacles to its improvement. It has acted thus in two different modes:—

First, by exciting in the public unfavourable prejudices.

And, secondly, by misleading Economists, both with respect to the object of their Science and the means of attaining it.

With respect to the first of these obstacles, it has often been made a matter of grave complaint against Political Economists, that they confine their attention to wealth, and disregard all consideration of happiness or virtue. It is to be wished that this complaint were better founded, but its general existence implies an opinion that it is the business of Political Economists not merely to state propositions, but to recommend actual measures, for on no other supposition could they be blamed for confining their attention to a single subject. No one blames a writer upon tactics for confining his attention to military affairs, or, from his doing so, infers that he recommends perpetual war. It must be admitted that an author who, having stated that a given conduct is productive of wealth, should, on that account alone, recommend it, or assume that, on that account alone, it ought to be pursued, would be guilty of the absurdity of implying that happiness and the possession of wealth are identical. But his error would consist not in confining his attention to wealth, but in confounding wealth with happiness. Supposing that error, and it is a very obvious one, to be avoided, the more strictly a writer confines his attention to his own Science, the more likely he is to extend its bounds.

Secondly, the confounding the Science of Political Economy with the Sciences and Arts to which it is subservient, has seduced Economists sometimes to undertake inquiries too vague to lead to any practical results, and sometimes to pursue the legitimate objects of the Science by means unfit for their attainment. To their extended view of the objects of Political Economy is to be attributed the undue importance which many Economists have ascribed to the collection of facts, and their neglect of the far more important process of reasoning accurately from the facts before them. We are constantly told that it is a Science of facts and experiment, a Science *avide de faits*. The practical applications of it, like the practical applications of every other Science, without doubt, require the collection and examination of facts to an almost indefinite extent. The facts collected as materials for the amendment of the poor-laws, and the opening of the trade to China, fill more than twice as many volumes as could be occupied by all the Treatises that have ever been written on Political Economy; but the facts on which the general principles of the Science rest may be stated in a very few sentences, and indeed in a very few words. But that the reasoning from these facts, the drawing from them correct conclusions, is a matter of great difficulty, may be inferred from the imperfect state in which the Science is now found after it has been so long and so intensely studied.

This difficulty arises partly from the extremely complicated nature of the subjects which it investigates, and the consequent abstractness and generality of its terms. A description, if it were possible, of all the different things which are designated by the word "wealth," or even by the less comprehensive word "capital," would fill an Encyclopædia. It arises partly, also, from the circumstance, that the terms which we are forced to use as signs for these abstractions are taken from ordinary language, commonly used in senses too wide or too narrow for scientific purposes. In the case, therefore, both of the writer and of the reader, they are often associated with ideas which are intended to be excluded, or separated from ideas which are meant to be comprehended. Thus, in ordinary language, the word capital is sometimes used as comprehending every species of wealth, and sometimes as confined to money.

If Economists had been aware that the Science depends more on reasoning than on observation, and that its principal difficulty consists not in the ascertainment of its facts, but in the use of its terms, we cannot doubt that their principal efforts would have been directed to the selection and consistent use of an accurate nomenclature. So far is this from having been the case, that it is only within a very short period that serious attention has been given to its nomenclature. *The Wealth of Nations* contains scarcely a definition: most of the modern French writers, and some indeed of our own, have not only neglected definitions, but have expressly reprobated their use; and the English Work which has attracted the most attention during the present century, Mr. Ricardo's *Principles of Political Economy*, is deformed by a use of words so unexplained, and yet so remote from ordinary usage, and from that of other writers on the same subject, and frequently so inconsistent, as to perplex every reader, and not unfrequently to have misled the eminent writer himself. We do not complain of all his innovations in language: such innovations are, for scientific purposes, frequently indispensable, and we shall be forced to make many ourselves. What we do complain of is, that his innovations, such, for instance, as the substitution of the word *value* for *cost*, are frequently unnecessary, and are almost always made without any warning to his readers; and that the same words, such, for example, as the adjectives *high* and *low*, when applied to wages, are used by him sometimes in their popular sense, as expressing an amount, and sometimes in a technical sense of his own, as expressing a proportion.

Our object in these remarks has been not only to account for the slow progress which has as yet been made by Political Economy, and to suggest means by which its advancement may be accelerated, but also to warn the reader of the nature of the following Treatise. He will find it consist, in a great degree, of discussions as to the most convenient use of a few familiar words. Such discussions it is impossible to render amusing, but we trust that they will be useful, by directing his attention to the great difficulties of the Science, though he may often disapprove our classification or nomenclature.

Wealth.

Having stated that the Science which we propose to consider, and to which we apply the term Political Economy, is the Science which treats of the nature, the production, and the distribution of wealth, our first business is to explain the meaning in which we use the word wealth.

Under that term we comprehend all those things, and those things only, which are transferable, are limited in supply, and are directly or indirectly productive of pleasure or preventive of pain; or, to use an equivalent expression, which are susceptible of *exchange;* (using the word exchange to denote hiring as well as absolute purchase;) or, to use a third equivalent expression, which have *value;* a word which, in a subsequent portion of this Treatise, we shall explain at some length, merely premising at present that we use it in its popular sense, as denoting the capacity of being given and received in exchange.

Of the three qualities which render any thing an article of wealth, or, in other words, give it value, the most striking is the power, direct or indirect, of producing pleasure, including under that term gratification of every kind, or of preventing pain, including under that term every species of discomfort. Unfortunately, we have no word which precisely expresses this power; *utility*, which comes nearest to it, being generally used to express the quality of preventing pain or of indirectly producing pleasure, as a means. We shall venture to extend the signification of that word, and consider it as also including all those things which produce pleasure directly. We must admit that this is a considerable innovation in English language. It is, however, sanctioned by Mr. Malthus, (*Definitions*, p. 234,) and has been ventured by M. Say in French, a language less patient of innovation than our own. Feeling the same difficulty, he has solved it in the same way by using the term *utilité* as comprehending every quality that renders any thing an object of desire. Attractiveness and desirableness have both been suggested to us as substitutes, but on the whole they appear to us more objectionable than *utility*, objectionable as we must admit that word to be.

Utility, thus explained, is a necessary constituent of value; no man would give any thing possessing the slightest utility for a thing possessing none; and even an exchange of two useless things would be, on the part of each party to the exchange, an act without a motive. Utility, however, denotes no intrinsic quality in the things which we call useful; it merely expresses their relations to the pains and pleasures of mankind. And, as the susceptibility of pain and pleasure from particular objects is created and modified by causes innumerable, and constantly varying, we find an endless diversity in the relative utility of different objects to different persons, a diversity which is the motive of all exchanges.

The next constituent of value is *limitation in supply.* It may appear inaccurate to apply this expression to any class of things, as it, in fact, belongs to all; there being nothing which, strictly speaking, is unlimited in supply. But, for the purposes of Political Economy, every thing may be considered as unlimited in supply *in its existing state*, of which a man may have as much as he pleases for the mere trouble of taking it into his possession. Thus the water of the open sea is, in our use of the term, unlimited in supply; any man who chooses to go for it may have as much of it as he pleases: that portion of it which has been brought to London is limited in supply, and is to be obtained not merely by going to the reservoir and taking possession of it, but by giving for it an equivalent. The copper ores which Sir John Franklin discovered on the shores of the Arctic Sea may be considered, *in their existing state*, as unlimited in supply; any man may have as much of them as he has strength and patience to extract. The extracted portion would be limited in supply, and therefore susceptible of value. Many things are unlimited in supply for some purposes, and limited for others. The water in a river is in general more than sufficient for all the domestic purposes for which it can be required; nobody pays therefore for permission to take a bucketfull: but it is seldom sufficient for all those who may wish to turn their mills with it; they pay, therefore, for that privilege.

It must be further observed that, for economical purposes, the term *limitation in supply* always involves the consideration of the causes by which the existing supply is limited. The supply of some articles of wealth is limited by insurmountable obstacles. The number of Raphael's pictures, or of Canova's statues, may be diminished, but cannot possibly be increased. There are others of which the supply may be increased to an indefinite extent. Such things may be considered as comparatively limited in supply, in proportion, not to the existing supply of each, but to the force of the obstacles opposed to their respective increase. It is supposed that there is now about forty-five times as much of silver extracted from the mines, and current in Europe, as there is of gold. Human exertion is the only means by which the supply of either can be increased, and they may both be increased by human exertion to an amount of which we do not know the limit. The obstacle, therefore, by which they are each limited in supply is, the amount of human exertion necessary to their respective increase. About sixteen times more exertion is necessary to produce an ounce of gold than an ounce of silver. The obstacle, therefore, which limits the supply of gold is sixteen times more powerful than that which limits the supply of silver. In our sense of the term, therefore, gold is only sixteen times more limited in supply than silver, though the actual weight of silver in Europe is forty-five times as great as that of gold. To take a more familiar example, the number of coats and waistcoats in England is perhaps about equal. The supply of each may be increased by human exertion to an indefinite extent; but it requires about three times as much exertion to produce a coat as to produce a waistcoat. As the obstacle, therefore, which limits the supply of coats is three times as forcible as that which limits the supply of waistcoats, we consider coats three times more limited in supply than waistcoats, though the existing supply of each may perhaps be equal. Whenever, therefore, we apply the words *limited in supply*, as a comparative expression, to those commodities of which the quantity can be increased, we refer to the comparative force of the obstacles which limit the respective supplies of the objects compared.

The third and last quality which a thing must possess to constitute it an article of wealth, or, in other words, to give it value, is *transferableness*, by which term (we are sorry to say, an unusual one) we mean to express that all or some portion of its powers of giving pleasure, or preventing pain, are capable of being transferred, either absolutely, or for a period. For this purpose it is obvious that it must be capable of appropriation; since no man can give what he cannot refuse. The sources of pleasure and preventives of pain which are absolutely incapable of appropriation are very few. We almost doubt whether there are any, and we are sure that the instances which are usually given are incorrect. "The earth," observes M. Say, *Econ. Pol.* liv. ii. ch. ix. "is not the only material agent with productive power, but it is the only one, or nearly so, that can be appropriated. The water of rivers and of the sea, which supplies us with fish, gives motion to our mills, and supports our vessels, has productive powers. The wind gives us force, and the sun heat, but happily no man can say, 'The wind and the sun belong to me, and I will be paid for their services.'" Now, in fact, air and sunshine are local. This is so obvious that it would be absurd to prove, by serious induction, that some situations have too much wind, and others too little, or that the sun's rays are more powerful productive agents in England than in Melville Island, or in the Tropics than in England. And as the land is every where capable of appropriation, the qualities of climate, which are attributes of that land, must be so too. What gives their principal value to the vineyards of the Côte Rotie, but the warmth of their sun? or to the houses which overlook Hyde Park, but the purity of their air? Rivers and the sea are equally unfortunate illustrations. Many of the rivers of England are not less strictly appropriated, and are far greater sources of wealth, than any equal superficies of land. When M. Say visited Lancashire, he must have found every inch of fall in every stream the subject of lease and purchase. And so far are the services of the sea from being incapable of appropriation, that, during the late war, £60,000 was sometimes paid for a licence to make use of it for a single voyage; and the privilege of fishing in particular parts of it has been the subject of wars and treaties.

The things of which the utility is imperfectly transferable may be divided into two great classes. The first comprises all those material objects which are affected by the peculiar mental associations, or adapted to the peculiar wants, of individuals. A mansion may flatter the pride of its owner as having been the residence of his ancestors, or be endeared to him as the scene of his childhood; or he may have built it in a form which pleases no eye, or laid it out in apartments that suit no habits but his own. Still its substantial powers of affording warmth and shelter will obtain him purchasers or tenants, though they may demand a reduction from the price in consequence of those very qualities which, with him, formed its principal merits. The palace of St. James's is full of comfort and convenience, and would supply a man of large fortune with an excellent residence; but the long suite of apartments within apartments, which is admirably adapted to holding a Court, would be a mere incumbrance to any but a royal personage. Any individual might hire Alnwick or Blenheim, and enjoy their mere beauty and magnificence, perhaps, more than their owners who have been long familiarized to them; but he could never feel the peculiar pleasure which they seem fitted to give to a Percy and a Churchill. There are many things, such as clothes and furniture, which sink in utility in the estimation of every one but their purchaser, from the mere fact of having changed hands. A hat or a table which has just been sent home does not appear to the purchaser less useful than when he saw it in the shop; but if he attempt to resell either, he will find that with the rest of the world it has sunk into the degraded rank of second-hand.

The second class of things imperfectly transferable includes the greater part, perhaps all, of our personal qualities. This classification, which places talents and accomplishments among the articles of wealth, may appear at first sight strange and inconvenient; it certainly is different from that of most Economists. We will therefore venture to illustrate it more fully.

Health, strength, and knowledge, and the other natural and acquired powers of body and mind, appear to us to be articles of wealth, precisely analogous to a residence having some qualities that are universally useful, and others peculiarly adapted to the tastes of its owner. They are limited in supply, and are causes of pleasure and preventives of pain far more effectual than the possession of Alnwick or of Blenheim. A portion of the advantages which arise from them are inseparably annexed to their possessor, like the associations of an hereditary property: another portion, and often a very large one, is as transferable as the palpable convenience of the mansion, or beauty of the gardens. What cannot be transferred are the temporary pleasure which generally accompanies the exercise of any accomplishment, and the habitual satisfaction arising from the consciousness of possessing it. What can be transferred are the beneficial results which follow from its having been employed during the period for which its services have been hired. If an Erskine or a Sugden undertakes my cause, he transfers to me, for that occasion, the use of all his natural and acquired ability. My defence is as well conducted as if I had myself the knowledge and the eloquence of an accomplished advocate. What he cannot transfer is the pleasure which he feels in the exercise of his dexterity; but how small is his pleasure compared to mine, if he succeeds for me! A passenger may envy the activity and intrepidity of the crew; they cannot actually implant in him their strength, or their insensibility to danger; but so far as these qualities are means towards an end, so far as they enable him to perform his voyage with quickness and safety, he enjoys the use of them as fully as if they belonged to himself. A hunter probably feels somewhat the same sort of pleasure in the chase which Erskine felt in court; and this pleasure cannot be transferred any more than his muscles or his lungs; but, so far as his strength, speed, and bottom are means towards the end of enabling his rider to keep up with the hounds, they can be purchased or hired as effectually as his bridle or saddle. In the greater part of the world a man is as purchasable as a horse. In such Countries the only difference in value between a slave and a brute consists in the degree in which they respectively possess the saleable qualities that we have been considering. If the question whether personal qualities are articles of wealth had been proposed in classical times, it would have appeared too clear for discussion. In Athens, every one would have replied that they, in fact, constituted the whole value of an εμψυχον οργανον. The only differences in this respect between a freeman and a slave are, first, that the freeman sells *himself*, and only for a period, and to a certain extent, the slave may be sold by others, and absolutely; and, secondly, that the personal qualities of the slave are a portion of the wealth of his master; those of the freeman, so far as they can be made the subjects of exchange, are a part of his own wealth. They perish indeed by his death, and may be impaired or destroyed by disease, or rendered valueless by any changes in the customs of the Country which shall destroy the demand for his services; but, subject to these contingencies, they are wealth, and wealth of the most valuable kind. The amount of revenue derived from their exercise in England far exceeds the rental of all the lands in Great Britain.

Of the three conditions of value, utility, transferableness, and limitation in supply, the last is by far the most important. The chief sources of its influence on value are two of the most powerful principles of human nature, the love of variety, and the love of distinction. The mere necessaries of life are few and simple. Potatoes, water, and salt, simple raiment, a blanket, a hut, an iron pot, and the materials of firing, are sufficient to support mere animal existence in this climate: they do, in fact, support the existence of the greater part of the inhabitants of Ireland; and in warmer Countries much less will suffice. But no man is satisfied with so limited a range of enjoyment. His first object is to vary his food; but this desire, though urgent at first, is more easily satisfied than any other, except perhaps that of dress. Our ancestors, long after they had indulged in considerable luxury in other respects, seem to have been contented with a very uniform though grossly abundant diet. And even now, notwithstanding the common declamation on the luxury of the table, we shall find that most persons, including even those whose appetites are not controlled by frugality, confine their principal solid food to but a few articles, and their liquids to still fewer.

The next desire is variety of dress; a taste which has this peculiarity, that, though it is one of the first symptoms that a people is emerging from the brutishness of the lowest savage life, it quickly reaches its highest point, and, in the subsequent progress of refinement, in one sex at least, diminishes until even the highest ranks assume an almost quaker-like simplicity.

Last comes the desire to build, to ornament, and to furnish: tastes which are absolutely insatiable where they exist, and seem to increase with every improvement in civilization. The comforts and conveniences which we now expect in an ordinary lodging are more than were enjoyed by people of opulence a century ago: and even a century ago a respectable tradesman would have been dissatisfied if his bed-room had been no better furnished than that of Henry VIII., which contained, we are told, only a bed, a cupboard of plate, a joint-stool, a pair of andirons, and a small mirror.* And yet Henry was among the richest and the most magnificent sovereigns of his times. Our great grandchildren perhaps will despise the accommodations of the present Age, and their poverty may, in turn, be pitied by their successors.

It is obvious, however, that our desires do not aim so much at quantity as at diversity. Not only are there limits to the pleasure which commodities of any given class can afford, but the pleasure diminishes in a rapidly increasing ratio long before those limits are reached. Two articles of the same kind will seldom afford twice the pleasure of one, and still less will ten give five times the pleasure of two. In proportion, therefore, as any article is abundant, the number of those who are provided with it, and do not wish, or wish but little, to increase their provision, is likely to be great; and, so far as they are concerned, the additional supply loses all, or nearly all, its utility. And in proportion to its scarcity the number of those who are in want of it, and the degree in which they want it, are likely to be increased; and its utility, or, in other words, the pleasure which the possession of a given quantity of it will afford, increases proportionally.

But strong as is the desire for variety, it is weak compared with the desire for distinction: a feeling which, if we consider its universality and its constancy, that it affects all men and at all times, that it comes with us from the cradle, and never leaves us till we go into the grave, may be pronounced to be the most powerful of human passions.

The most obvious source of distinction is the possession of superior wealth. It is the one which excites most the admiration of the bulk of mankind, and the only one which they feel capable of attaining. To seem more rich, or, to use a common expression, to keep up a better appearance, than those within their own sphere of comparison, is, with almost all men who are placed beyond the fear of actual want, the ruling principle of conduct. For this object they undergo toil which no pain or pleasure addressed to the senses would lead them to encounter; into which no slave could be lashed or bribed. But this object is attained by appearances, and, indeed, cannot be attained by any thing else. All the gold in the Pactolus, even if the Pactolus were as rich as when Midas had just washed in it, would obviously confer no distinction on the man who was unable to exhibit it. The only mode by which wealth can be exhibited is, by the apparent possession of some object of desire which is limited in supply. Mere limitation of supply, indeed, unless there be some other circumstance constituting the article in question an object of desire, or, in other words, giving it utility, is insufficient. This circumstance must be its having some quality to which some person beside the owner annexes the notion of utility. The original manuscript of every schoolboy's exercise is as limited in supply as any thing can be, but there is nothing to make it an object of desire after it has served its purpose in school. It is merely a blotted manuscript, unique certainly, but valueless. But if the original manuscript of the *Wealth of Nations* could be discovered, it would excite an interest throughout Europe. Curiosity would be eager to trace the first workings of a mind whose influence will be felt as long as civilized society endures. It might, perhaps, be purchased by some ignorant collector only for the purposes of ostentation, but it could not serve even those purposes unless recommended by some circumstance beyond mere singularity.

---

* Henry, *History of Great Britain*, book vi. ch. vii.

It is impossible, however, to conceive any thing more trifling or more capricious than the circumstances which may make a thing an object of desire, and therefore, in our extended use of that word, give to it utility when its supply is narrowly limited.

The substance which at present is the greatest object of desire, and of which, therefore, a given quantity will exchange for the greatest quantity of all other things, is the diamond. A bracelet belonging to the King of Persia, the stones in which do not weigh two ounces, is said to be worth a million sterling. Now, a million sterling would command the whole labour of about thirty thousand English families for a year. If that labour were employed in producing and reproducing commodities for the purposes of sale, it would probably give for ever a clear annual income equal to the labour of three thousand families, or twelve thousand individuals. It would place at the disposal of its owner all the commodities that could be produced by all the labour of all the inhabitants of a considerable town. And a few pieces of mineral, not weighing two ounces, capable of gratifying no sense but the sight, and which any eye would be tired of looking at for a minute, is invested by our caprice with a value equal to that of the commodities which would give comfortable support to thousands of human beings in an advanced state of civilization. Hardness and brightness must have been the qualities which first attracted notice to the diamond. They enabled it to please the eye and adorn the person, and thus associated with it the notion of utility. But a diamond weighing an ounce is not found once in a century; there are not five such known to exist. The possession of an object of desire so limited in supply soon became one of the most unequivocal proofs of wealth. And, as to appear rich is the ruling passion of the bulk of mankind, diamonds will probably continue the objects of eager competition while the obstacles that limit their supply are undiminished. If a Sindbad should discover a valley of diamonds, or we should succeed in manufacturing them from charcoal, they will probably be used only as ornaments for savages, playthings for children, and as affording tools and raw materials for some of the Arts; and we may send cargoes of diamonds to the coast of Guinea to be bartered for equal quantities of ivory or gum.

Value.

Value.

Our definition of wealth, as comprehending all those things, and those things only which have *value*, requires us to explain at some length the signification which we attribute to the word value; especially as the meaning of that word has been the subject of long and eager controversy. We have already stated that we use the word value in its popular acceptation, as signifying that quality in any thing which fits it to be given and received in exchange; or, in other words, to be lent or sold, hired or purchased.

So defined, value denotes a relation reciprocally existing between two objects, and the precise relation which it denotes is the quantity of the one which can be obtained in exchange for a given quantity of the other. It is impossible, therefore, to predicate value of any object, without referring, expressly or tacitly, to some other object or objects in which its value is to be estimated; or, in other words, of which a certain quantity can be obtained in exchange for a certain quantity of the object in question.

We have already observed that the substance which at present is most desired, or, in other words, possesses the highest degree of value, is the diamond. By this we meant to express that there is no substance of which a given quantity will exchange for so large a quantity of every other commodity. When we wished to state the value of the King of Persia's bracelet, we stated first the amount of gold, and afterwards of English labour, which it would command in exchange. If we had attempted to give a perfect account of its value, we could have done so only by enumerating separately the quantity of every other article of wealth which could be obtained in exchange for it. Such an enumeration, if it could have been given, would have been a most instructive commercial lesson, for it would have shown not only the value of the diamond in all other commodities, but the reciprocal value of all other commodities in one another. If we had ascertained that a diamond weighing an ounce would exchange for one million five hundred thousand tons of Hepburn coal, or one hundred thousand tons of Essex wheat, or two thousand five hundred tons of English foolscap paper, we might have inferred that the coal, wheat, and paper would mutually exchange in the same proportions in which they were exchangeable for the diamond, and that a given weight of paper would purchase six hundred times as much coal, and forty times as much wheat.

The causes which determine the reciprocal values of commodities, or, in other words, which determine that a given quantity of one shall exchange for a given quantity of another, must be divided into two sets; those which occasion the one to be limited in supply and useful, (using that word to express the power of occasioning pleasure and preventing pain,) and those which occasion those attributes to belong to the other. In ordinary language, the *force* of the causes which give utility to a commodity is generally indicated by the word *demand;* and the *weakness* of the obstacles which limit the quantity of a commodity by the word *supply.*

Thus the common statement that commodities exchange in proportion to the demand and supply of each, means that they exchange in proportion to the force or weakness of the causes which give utility to them respectively, and to the weakness or force of the obstacles by which they are respectively limited in supply.

Unfortunately, however, the words demand and supply have not been always so used. Demand is sometimes used as synonymous with consumption, as when an increased production is said to generate an increased demand; sometimes it is used to express not only the desire to obtain a commodity, but the power to give the holder of it something which will induce him to part with it. "A demand," says Mr. Mill, *Political Economy,* p. 23, 3d edition, "means the will to purchase and the power of purchasing." Mr. Malthus, *Definitions in Political Economy,* p. 244, states that "demand for commodities has two distinct meanings: one in regard to its extent, or the quantity of commodities purchased; the other in regard to its intensity, or the sacrifice which the demanders are able and willing to make in order to satisfy their wants."

Neither of these expressions appears to be consistent with common usage. It must be admitted that the word demand is used in its ordinary sense when we say that a deficient wheat harvest increases the demand for oats and barley. But this proposition is not true if we use the word demand in any other sense than as expressing the increased utility of oats and barley; or, in other words, the increased desire of the community to obtain them. The deficiency of wheat would not give to the consumers of oats and barley any increased power of purchasing them, nor would the quantity purchased or consumed be increased. The mode of consumption would be altered; instead of being applied to the feeding of horses, or to the supply of stimulant liquids, a certain portion of them would be used as human food. And, as the desire to eat is more urgent than the desire to feed horses, or drink beer or spirits, the desire to obtain oats and barley, or, in other words, the pleasure given, or the pain averted, by the possession of a given quantity of them, or, in other words, the *utility* of a given quantity of them, would increase. A fact which, in ordinary language, would be expressed by saying, that the demand for them was increased.

But though the vagueness with which the word demand has been used renders it an objectionable term, it is too useful and concise to be given up; but we shall endeavour never to use it in any other signification than as expressing the utility of a commodity; or, what is the same, for we have seen that all utility is relative, the degree in which its possession is desired.

We cannot complain of equal vagueness in the use of the word supply. In ordinary language, as well as in the writings of Political Economists, it is used to signify the quantity of a commodity actually brought to market. The complaint is, not that the word supply has been used in this sense, but that, when used in this sense, it has been considered as a cause of value, except in a few cases, or for very short periods. We have shown, in the examples of coats and waistcoats, and gold and silver, that the reciprocal value of any two commodities depends, not on the quantity of each brought to market, but on the comparative force of the obstacles which in each case oppose any increase in that quantity. When, therefore, we represent increase or diminution of supply as affecting value, we must be understood to mean not a mere positive increase or diminution, but an increase or diminution occasioned by a diminution or increase of the obstacles by which the supply is limited.

To revert to our original proposition, the reciprocal values of any two commodities must be determined by two sets of causes; those which determine the demand and supply of the one, and those which determine the demand and supply of the other. The causes which give utility to a commodity and limit it in supply may be called the *intrinsic* causes of its value; those which limit the supply and occasion the utility of the commodities for which it is to be exchanged, may be called the *extrinsic* causes of its value. Gold and silver are now exchanged for one another in Europe in the proportion of one ounce of gold for about sixteen ounces of silver. This proportion must arise partly from the causes which give utility to gold and limit its supply, and partly from those which create the utility and limit the supply of silver. When talking of the value of gold we may consider the first set of causes as influencing its general value, since they affect its powers of commanding every commodity in exchange. The second set of causes affect gold only so far as it is to be exchanged for silver, which may be called one of its specific values; the aggregate of its specific values forming its general value. If while the causes which give utility to silver and limit it in supply were unaltered, those which affect gold should vary; if, for instance, fashion should require every well-dressed man to have all his buttons of pure gold, or the disturbances in South America should permanently stop all the gold works of Brazil and Colombia, and thus (as would be the case) intercept five-sixths of our supplies of gold, the reciprocal values of gold and silver would in time be materially varied. Though silver would be unaltered both as to its utility and as to its limitation in supply, a given quantity of it would exchange for a less quantity of gold, in the proportion perhaps of twenty to one, instead of sixteen to one. As between one another the rise and fall of gold and silver would precisely correspond, silver would fall and gold would rise one-fourth. But the fall of silver would not be general but specific; though fallen as estimated in gold, it would command precisely the same quantities as before of all other commodities. The rise of gold would be general; a given quantity of it would command one-fourth more not only of silver, but of all other commodities. The holder of a given quantity of silver would be just as rich as before for all purposes except the purchase of gold; the holder of a given quantity of gold would be richer than before for all purposes.

The circumstances by which each different class of commodities is invested with utility and limited in supply are subject to perpetual variation. Sometimes one of the causes alone varies. Sometimes they both vary in the same direction; sometimes in opposite directions. In the last case the opposite variations, wholly or partially, neutralize one another.

The effects of an increased demand concurrent with increased obstacles to supply, and of diminished demand concurrent with increased facility of supply, are well exemplified by hemp. Its average price before the revolutionary war, exclusive of duty, did not exceed £30 per ton. The increased demand occasioned by a maritime war, and the natural obstacles to a proportionate increase of supply, raised it, in the year 1796, to above £50 a ton; at about which price it continued during the next twelve years. But in 1808, the rupture between England and the Baltic powers, the principal source of our supplies, suddenly raised it to £118 a ton, being nearly four times the average price in peace. At the close of the war, both the extraordinary demand and the extraordinary obstacles to the supply ceased together, and the price fell to about its former average.

We have already stated that the utility of a commodity, in our extended sense of the term utility, or, in other words, the demand for it as an object of purchase or hire, is principally dependent on the obstacles which limit its supply. But there are many cases in which, while the existing obstacles remain unaltered, the demand is affected by the slightest suspicion that their force may at a future period be increased or diminished. This occurs with respect to those commodities of which the supply is not susceptible of accurate regulation, but is afforded either in uncertain quantities and at stated periods, between which it cannot be increased or diminished,—in the case for instance of the annual products of the earth,—or is dependent on our relations with foreign Countries. If a harvest deficient by one-third should occur, that deficiency must last for a whole year, or be supplied from abroad at an extravagant cost. If we should go to war with Russia, the obstacles to the supply of hemp would be increased while the war lasted. In either case the holders of corn or hemp would obtain great profits. In all rich Countries, and particularly in our own, there is a great number of persons who have large masses of wealth capable of being suddenly applied to the purchase of any given objects. The instant such persons suspect that the obstacles to the supply of any article are likely to be increased, they are anxious to become holders of it. They enter the market as new demanders; the price rises, and the mere fact that it has risen is a cause of its rising further. The details of commerce are so numerous, the difficulty of obtaining early and accurate information is so great, and the facts themselves are so constantly changing, that the most cautious merchants are often forced to act upon very doubtful premises; and the imprudent, dazzled by the chance of an enormous gain, which will be their own, and little restrained by the fear of a loss which may principally fall upon their creditors, are often ready to act upon scarcely any premises at all. They see that the price of some article has risen, and they suppose that there must be some good cause for it. They see that if they had purchased a month ago, they would have been gainers now, and conclude that if they purchase now they will be gainers a month hence. So far is this reasoning, if it can be called reasoning, carried, that a rise in the price of any one important commodity is generally found to occasion a rise in the price of many others. "A" (thinks a speculator) "bought hemp before the price had risen and has resold it at a profit. Cotton has not yet risen, nor do I see clearly why it should rise, any more than I see why hemp should have risen, but it probably will rise like hemp, therefore I will purchase."

Those who are not practically conversant with commercial transactions, and who are probably accustomed to consider our merchants and capitalists as men of sober minds, and cautious conduct, may perhaps think that we exaggerate the influence of imagination over judgment when we suppose that large fortunes are often risked on such reasoning as this. We cannot support our view better than by the authority of Mr. Tooke, a merchant of great talent and knowledge, and, at the period when he wrote, forced, for his own safety, to watch narrowly the phenomena which he described. The passages which we subjoin are taken from his account of the circumstances which occasioned the extraordinary rise of prices in the beginning of 1825. "The close of each year[*] is the period at which, by annual custom, the stocks of goods on hand, and the prospects of supply and consumption for the coming season, are stated and reasoned upon by merchants and brokers in circular letters addressed to their correspondents and employers. By these circulars it appeared (at the close of 1824) that, of some important articles, the stock on hand fell short of that at the close of the preceding year. From this the conclusion was more or less plausibly deduced, that the rate of the annual consumption of those articles was outrunning the rate of the annual supply, and that an advance in price ought to take place; and at the same time, there were, as in the case of cotton and silk, confident reports of the failure of crops or other causes which would inevitably diminish the forthcoming supply. Expectation of scarcity was thus combined with actual deficiency in exciting the spirit of speculation. This was directed in the first instance to the articles which, upon fair mercantile grounds, justified and called for some advance in price, inasmuch as the rate of the consumption of them had outrun the average rate of supply. The rise, however, which would have been requisite to increase the supply, or to diminish the consumption, would, in most of the cases in question, have been trifling.

"But when speculation is once on foot, the rise of any one article may not only be in a ratio far greater than the occasion really calls for, but may cause indirectly a rise in other commodities.

"The impulse, therefore, to a rise being given, and every succeeding purchaser having realized, or appearing to have the power of realizing, a profit, a fresh inducement appeared in every step of the advance to bring forward new buyers. These were no longer such only as were conversant with the market: many persons were induced to go out of their own line, and to embark their funds, or stretch their credit, with a view to engage in what was represented to them by the brokers a certain means of realizing a great and immediate gain.

"Cotton exhibited the most extraordinary instance of speculation carried beyond all reasonable bounds. Silk, wool, and some other articles in which some advance was justified by the relative state of the supply and demand, became the subjects of a speculative anticipation, and advanced much beyond the occasion, as the event proved, though not in so great a degree as cotton.

"Never did the public, that part of it at least which entered into the vortex of the operations in question, exhibit so great a degree of infatuation, so complete an abandonment of all the most ordinary rules of mercantile reasoning since the celebrated bubble year 1720, as it did in the latter part of 1824, and in the first three or four months of 1825.

"The speculative anticipation of an advance was no longer confined to articles which presented a plausible ground for some rise however small. It extended itself to articles which were not only not deficient in quantity but which were actually in excess. Thus coffee, of which the stock was increased compared with the average of former years, advanced from 70 to 80 per cent. Spices rose in some instances from 100 to 200 per cent. without any reason whatever, and with a total ignorance on the part of the operators of every thing connected with the relation of the supply to the consumption.

"In short, there was hardly an article of merchandise which did not participate in the rise. For it became the business of the speculators or the brokers, who were interested in raising and keeping up prices, to look minutely through the general Price Currents with a view to discover any article which had not advanced, in order to make it the subject of anticipated demand.

"If a person not under the influence of the prevailing delusion ventured to inquire for what reason any particular article had risen, the common answer was, 'Every thing else has risen, and therefore this ought to rise.'"

When we consider that the supply of large classes of commodities is dependent on our amicable or hostile relations with foreign States, and on the commercial and financial legislation both of those States and of our own Country, and that the supply of still larger classes is dependent not only on those contingencies, but on the accidents of the seasons,—and when we consider how the demand is affected not merely by the existing, or the anticipated obstacles to the supply, but often by a spirit of speculation as blind as that of a gambler ignorant of the odds and even of the principles of his game,—it is obvious that the general value of all commodities, the quantity of each which will exchange for a given quantity of every other, can never remain the same for a single day. Every day there will be a variation in the demand or the supply of one or more of the innumerable classes of commodities which are the objects of exchange in a commercial Country. A given quantity of the commodity which has varied will consequently exchange for a greater or a less quantity of all other commodities. All other commodities, therefore, will have varied in value as estimated in the first-mentioned commodity. It is as impossible for one commodity to remain perfectly unaltered in value while any other is altered, as it would be for a light-house to keep at the same distance from all the ships in a harbour while any one of them should approach it or recede.

---

[*] *Considerations on the State of the Currency*, p. 43.

But it may be asked, what do we mean when we say that a commodity has, for a given period, remained *steady* in value?

The question must be answered by referring to the different effects produced on the value of a commodity by an alteration in the intrinsic, or an alteration in the extrinsic, causes on which value depends. If the causes which give utility to a commodity and limit its supply, and which we have called the intrinsic causes of its value, are altered, the rise or fall in its value will be general. A given quantity of it will exchange for a greater or a less quantity than before of every other commodity which has not also varied at the same time, in the same direction, and in the same degree; a coincidence which rarely occurs. Every other commodity must also rise or fall in value as estimated in the first-mentioned commodity, but not generally.

The fluctuations in value to which a commodity is subject by alterations, in what we have called the extrinsic causes of its value, or, in other words, by alterations in the demand or supply of other commodities, have a tendency, like all other extensive combinations of chances, to neutralize one another. While it retains the same utility, and is limited in supply by the same causes, a given quantity of it, though it may exchange for a greater or a less quantity of different specific commodities, will in general command the same average quantity as before of the general mass of commodities; what it gains or loses in one direction being made up in another. It may be said, without impropriety, therefore to remain steady in value. But the rise or fall in value which a commodity experiences in consequence of an alteration in its utility, or in the obstacles to its supply, is, in fact, entirely uncompensated. It is compensated only with regard to those commodities of which the utility or the supply has also varied at the same time and in the same direction. And as quite as many are likely to experience a similar variation, but in an opposite direction, there is really *no* compensation. A commodity, therefore, which is strikingly subject to such variations, is properly said to be unsteady in value.

But we may be asked to account for another and not unfrequent statement, that at particular periods *all* commodities have been observed to rise or fall in value. Literally taken, this statement involves a contradiction in terms, since it is impossible that a given quantity of every commodity should exchange for a greater or a less quantity of every other. When those who make this statement have any meaning, they always tacitly exclude some one commodity, and estimate in that the rise or fall of all others. The excluded commodity is, in general, money or labour.

Estimated in labour, all commodities, money included, have fallen in value in England since the XVIth Century. It is scarcely possible to mention one of which a given quantity will not purchase less labour than it did at the close of Elizabeth's reign; estimated in money, almost all commodities, labour included, have fallen in England since the termination of the late war.

The last remark which we shall now make on value is, that, with a very few exceptions, it is strictly local. A ton of coal at the bottom of the pit near Newcastle is perhaps worth 2*s.* 6*d.*, at the pit's mouth it is perhaps worth 5*s.*, at ten miles off 7*s.*, at Hull 10*s.* By the time the collier has reached the Pool, its cargo is seldom worth less than 16*s.* a ton; and the inhabitant of Grosvenor Square may perhaps think himself fortunate if he can fill his coal cellars at 25*s.* a ton.* A ton of coal, though physically identical, must be considered, for economical purposes, as a different commodity at the bottom of the pit and at its mouth, in Hull and in Grosvenor Square. At every different stage of its progress it is limited in supply by different obstacles, and consequently exchangeable for different things and in different proportions. Supposing that at Newcastle a ton of the best wheat is now worth about twenty tons of the best coal: the same wheat and coal at the west end of London may probably exchange in the proportions of about four tons of coal for one of wheat. At Odessa, they may perhaps exchange about weight for weight.

Whenever, therefore, we speak of the value of a commodity, it is necessary to state the locality both of the commodity in question, and of the commodity in which its value is estimated. And in most cases we shall find their respective proximity to the places where they are respectively to be made use of one of the principal constituents of their respective values. The purchaser of the distant commodity has to consider the labour of transporting it to the place of consumption, the time for which that labour must be paid in advance, and the taxation, and the risk of injury or loss to which it may be subject in its transit. Nor is this all. He must also consider the danger that its quality may not correspond with the description or sample which guided him in making the purchase. The whole expense and risk attending the transport of a diamond from Edinburgh to London are but trifling; but its value is so dependent on its form and lustre, and those are qualities as to which it is so difficult to satisfy any purchaser who cannot ascertain them by inspection, that it would be difficult to obtain in London a fair price for a diamond in Edinburgh. Again, though a given quantity of coal from a given mine is generally of an ascertained quality, yet the expense, loss of time, risk, and taxation, which must be incurred in its transport from Newcastle to Grosvenor Square, are such that a ton of coal, when it has reached Grosvenor Square, may be of nearly five times the value which it bore at Newcastle.

Objections to Definition of Wealth considered.

Objections to definition of wealth considered.

The definition of wealth, as comprehending all those things, and those things only, which have value, or, in other words, which may be purchased or hired, does not, we believe, precisely agree with that adopted by any Economist except Archbishop Whately.

---

* These prices are merely assumed for the purpose of illustration.

Objections to definition of wealth considered.

The principal differences are these: some writers confine the term wealth to what have been termed material products; some to those things which have been produced or acquired by human labour; and some object to the ideas of value or exchange being introduced into the definition of wealth.

The question whether the things which have been called immaterial ought to be considered articles of wealth, we shall consider when we treat of production.

Some of the writers who, expressly or impliedly, restrict the term wealth to the things, the production or appropriation of which has cost human labour, as for instance Mr. Mill, Mr. M'Culloch, Colonel Torrens, Mr. Malthus, and M. Flores-Estrada, appear to suppose that a definition so restricted will comprise every thing that can properly be termed wealth; others, among whom is Mr. Ricardo, admit that there are some things falling within that term which have not been acquired by human exertion, but think them so few or unimportant that it is better to omit them than to disorder the symmetry of the Science by extending it to any thing that is not the result of labour.

The former doctrine is clearly stated in the following passages from Mr. Malthus, Colonel Torrens, and Mr. M'Culloch.

"Wealth. The material things necessary, useful, or agreeable to man, which have required some portion of human exertion to appropriate or produce."*

"Wealth, considered as the object of economical Science, consists of those material articles which are useful or desirable to man, and which it requires some portion of voluntary exertion to procure or to preserve. Thus two things are essential to wealth: the possession of utility, and the requiring some portion of voluntary exertion or labour. That which has no utility, which serves neither to supply our wants, nor to gratify our desires, is as the dust beneath our feet, or as the sand upon the shore, and obviously forms no portion of our wealth; while, on the other hand, things which possess the highest utility, and which are even necessary to our existence, come not under the denomination of wealth, unless to the possession of utility be superadded the circumstance of having been procured by some voluntary exertion. Though the air which we breathe and the sunbeams by which we are warmed are in the highest degree useful and necessary, it would be a departure from the precision of language to denominate them articles of wealth. But the bread which appeases the cravings of hunger, and the clothing which protects us from the rigour of the season, though not more indispensably requisite than the former, are with propriety classed under the term wealth; because to the possession of utility they add the circumstance of having been produced by labour."†

"Labour is the only source of wealth. Nature spontaneously furnishes the matter of which all commodities are made; but until labour has been expended in appropriating matter, or in adapting it to our use, it is wholly destitute of value, and is not, nor ever has been, considered as forming wealth. Place us on the banks of a river, or in an orchard, and we shall inevitably perish of thirst or hunger, if we do not, *by an effort of industry*, raise the water to our lips, or pluck the fruit from its parent tree.

"An object which it does not require any portion of labour to appropriate or to adapt to our own use may be of the very highest utility, but, as it is the free gift of nature, it is utterly impossible it can possess the smallest value."*

Mr. M'Culloch appears to use the word labour as including all voluntary action. And without doubt, if we use the word labour in so extended a sense, it is true that labour is almost necessarily incidental to the *enjoyment* of wealth. If it be an act of industry to gather an apple, it is equally an act of industry to raise it from one's plate; and every guest at a festival earns his food by the labour which he exerts in appropriating his own portion. Such attempts as these to bend facts and language into accordance with hasty generalization have thrown on Political Economy a degree of ridicule which is one of the principal obstacles to its progress.

Mr. Malthus, Colonel Torrens, and the other Economists who consider labour, using that word in its popular sense, as a necessary constituent of wealth, appear to have been led to that opinion by observing, first, that some quality besides mere utility is necessary to value; secondly, that all those things which are useful, and are acquired by labour, are valuable; and thirdly, that almost every thing which is valuable *has* required some labour for its acquisition. But the fact that that circumstance is not essential to value will be demonstrated if we can suppose a case in which value could exist without it. If, while carelessly lounging along the sea-shore, I were to pick up a pearl, would it have no value? Mr. M'Culloch would answer that the value of the pearl was the result of my appropriative industry in stooping to pick it up. Suppose then that I met with it while eating an oyster? Supposing that aerolithes consisted of gold, would they have no value? Or, suppose that meteoric iron were the only form in which that metal were produced, would not the iron supplied from heaven be far more valuable than any existing metal? It is true that, wherever there is utility, the addition of labour as necessary to production constitutes value, because, the supply of labour being limited, it follows that the object, to the supply of which it is necessary, is by that very necessity limited in supply. But any other cause limiting supply is just as efficient a cause of value in an article as the necessity of labour to its production. And, in fact, if all the commodities used by man were supplied by nature without any intervention whatever of human labour, but were supplied in precisely the same quantities as they now are, there is no reason to suppose either that they would cease to be valuable, or would exchange in any other than their present proportions.

The reply to Mr. Ricardo is, first, that the articles of wealth which do not owe the principal part of their value to the labour which has been bestowed on their respective actual production, form, in fact, the bulk of wealth instead of a small and unimportant portion of it; and secondly, that, as limitation of supply is essential to the value of labour itself, to assume labour, and exclude limitation of supply, as the condition on which value depends, is not only to substitute a partial for a general cause, but pointedly to exclude the very cause which gives force to the cause assigned.

We have lastly to consider the objections which have been raised to the definition of wealth as a general name for the things which have value. Those who use the

Objections to definition of wealth considered.

word value as synonymous with *cost*, or as comprehending whatever is useful, of course object to its introduction into the definition of wealth; and so should we do if we used the word value in either of those senses. But other writers, using the word value in its popular sense, have objected that, according to the definition which we have adopted, the same thing will be wealth to one person and not to another. This consequence is evident; and it is evident that even to the same person the same quality may be wealth under some circumstances, and not so under others. The knowledge of English law is profitable in England, that of French law in France; if an English lawyer, with no other property than his knowledge, were to settle in France, or a French lawyer in England, he would find himself instantly reduced from affluence to poverty. The power of telling long stories is a source of profit in Asia, but valueless in Europe. According to our nomenclature, therefore, it would be wealth in Persia, and cease to be so in England. If an actress should embrace a religious sect of which the tenets should be incompatible with the stage, her vocal and dramatic talents would no longer be exchangeable, she would no longer be able to let them out by the evening. We should say, therefore, that they had ceased to be a part of her wealth. But we are at a loss to conceive how the power of making this distinction is an objection to the language in question. It seems to be its principal convenience.

Again, Colonel Torrens supposes a solitary family, or a nation in which each person should consume only his own productions, or one in which there should be a community of goods, and urges, as a *reductio ad absurdum*, that in these cases, though there might be an abundance of commodities, as there would be no exchanges, there would, in our sense of the term, be no wealth. The answer is, that, for the purposes of Political Economy, there would be no wealth: for, in fact, in such a state of things, supposing it possible, the Science of Political Economy would have no application. In such a state of society, Agriculture, Mechanics, or any other of the Arts which are subservient to the production of the commodities which are, with us, the subjects of exchange, might be studied, but the Science of Political Economy would not exist. We may add, that if the common usage which identifies wealth with the things which have value is a convenient one in all the forms which human nature really exhibits, it is no objection to it that it would not be convenient in a state of society of which we have no experience.

Statement of the four Elementary Propositions of the Science.

Statement of the elementary propositions of the Science.

We have already stated that the general facts on which the Science of Political Economy rests are comprised in a few general propositions, the result of observation or consciousness. The propositions to which we then alluded are these:

1. *That every man desires to obtain additional wealth with as little sacrifice as possible.*
2. *That the population of the world, or, in other words, the number of persons inhabiting it, is limited only by moral or physical evil, or by fear of a deficiency of those articles of wealth which the habits of the individuals of each class of its inhabitants lead them to require.*
3. *That the powers of labour, and of the other instruments which produce wealth, may be indefinitely increased by using their products as the means of further production.*
4. *That, agricultural skill remaining the same, additional labour employed on the land within a given district produces in general a less proportionate return, or, in other words, that though, with every increase of the labour bestowed, the aggregate return is increased, the increase of the return is not in proportion to the increase of the labour.*

The first of these propositions is a matter of consciousness, the three others are matter of observation. As the first and second involve little use of the peculiar abstractions of Political Economy, except those implied in the term wealth, and may therefore be explained with little recourse to its peculiar nomenclature, we shall consider them immediately; leaving the third and fourth for discussion in a subsequent part of this Treatise. They are however so nearly self-evident, that we will venture in the mean time to assume their truth. No one who reflects on the difference between the unassisted force of man, and the more than gigantic powers of capital and machinery, can doubt the former proposition; and, to convince ourselves of the other, it is necessary only to recollect that, if it were false, no land except the very best could ever be cultivated: since, if the return from a single farm were to increase in full proportion to any amount of increased labour bestowed on it, the produce of that one farm might feed the whole population of England.

General Desire for Wealth.

General desire for wealth.

In stating that every man desires to obtain additional wealth with as little sacrifice as possible, we must not be supposed to mean, that every body, or indeed any body, wishes for an indefinite quantity of every thing; still less as stating that wealth, though the universal, either is, or ought to be, the principal object of human desire. What we mean to state is, that no person feels his whole wants to be adequately supplied; that every person has some unsatisfied desires which he believes that additional wealth would gratify. The nature and the urgency of each individual's wants are as various as the differences in individual character. Some may wish for power, others for distinction, and others for leisure; some require bodily, and others mental amusement; some are anxious to produce important advantage to the public; and there are few, perhaps there are none, who, if it could be done by a wish, would not benefit their acquaintances and friends. Money seems to be the only object for which the desire is universal; and it is so, because money is abstract wealth. Its possessor may satisfy at will his ambition, or vanity, or indolence, his public spirit or his private benevolence; may multiply the means of obtaining bodily pleasure, or of avoiding bodily evil, or the still more expensive amusements of the mind. Any one of these pursuits would exhaust the largest fortune within the limits of individual acquisition; and, as all men would engage in some of them, and many in all, the desire for wealth must be insatiable, though the modes in which different individuals would employ it are infinitely diversified.

An equal diversity exists in the amount and the kind of the sacrifices which different individuals, or even the same individual, will encounter in the pursuit of wealth.

General desire for wealth.

And not only is the same sacrifice more severe to one than to another, as some will not give up ease or leisure for study, others good air and a country life, and others recreation and society, but the absolute desire for wealth on the one hand, and the absolute will to encounter toils or privations in its pursuit on the other, are stronger in some men than in others. These differences form some of the principal distinctions in individual and national character. Experience, however, shows, and indeed it might have been predicted *à priori*, that the greatest and longest continued sacrifices will be made in those Countries in which property is most secure, and the road to social eminence is the most open. The inhabitants of Holland and of Great Britain, and of the Countries that have derived their institutions from Great Britain, the nations which up to the present time have best enjoyed those advantages, have up to the present time been the most ardent and the most successful in the pursuit of opulence. But even the Indians of Mexico, though their indolence makes them submit to poverty under which an Englishman would feel life a burthen, would willingly be rich if it cost them no trouble.

It may be necessary, however, to explain our motives for dwelling on so much that is self-evident. Our first reason is, that the proposition in question, though we are not aware that any one has thought that it required to be formally stated, is assumed in almost every process of economical reasoning. It is the corner-stone of the doctrine of wages and profits, and, generally speaking, of exchange. In short, it is in Political Economy what gravitation is in Physics, or the *dictum de omni et nullo* in Logic: the ultimate fact beyond which reasoning cannot go, and of which almost every other proposition is merely an illustration. In an attempt to state the evidence on which the Science rests, it appeared to us improper to omit its foundation, though at the hazard of appearing to take up our reader's time in defending what it may be supposed that nobody ever thought of questioning.

But, in the second place, this proposition, apparently self-evident, *has* been impliedly questioned. It is directly opposed to a doctrine of considerable popularity, and supported by great names,—we mean the doctrine of over-production or *universal* glut.

By the word glut is meant the production of a given commodity in an abundance, either absolutely beyond the desires of its intended consumers, or beyond the amount for which they are able and willing to offer in exchange equivalents sufficient to induce the producer to continue his operations. Books are, perhaps, the commodities most subject to gluts. The proportionate expenses of printing and advertising increase so rapidly, if the number of copies printed be much reduced, and authors are so little subject to underrate the probable demand for their labours, that scarcely any edition consists of less than two hundred and fifty copies, and very few of less than five hundred. But we have seen calculations showing that not in one case out of two hundred are all the copies sold off at the price at which they originally came out. In ordinary cases, from fifty to one hundred are sold in the first year, and thirty or forty in the second; by the end of which time the book has been forgotten, and the unsold copies are put up to sale at periodical auctions among the booksellers. The best that can happen to them is to be purchased on this occasion in order to be again offered to the public; but the majority of Works are found to be worth purchase not as books, but as paper. They are unsold at the trade sales, and find their way

> *In vicum vendentem thus et odores*
> *Et piper, et quidquid chartis amicitur ineptis.*

We have selected books as affording an illustration of a glut arising from a miscalculation not of the ability, but of the willingness of purchasers. The opening of a new trade is generally followed by gluts occasioned by miscalculations of both. Every one must recollect, when Brazil and Spanish America first became accessible, our exports of skaits, and fire-irons, and warming pans to the tropics. And, until their real poverty was known, we continued to fill their warehouses with cargoes, adapted indeed to their wants, but far beyond their means. Miscalculations of this kind must obviously be of frequent occurrence; and perhaps what ought to excite our surprise is, not the extent to which they prevail, but the degree in which they are avoided. But it appears clear that they can arise only from one or the other of two causes: either from the articles of wealth, with respect to which the glut exists, having been prepared for persons who do not want them, or from those persons not being provided with other articles of wealth, suited to the desires of the producers of the first-mentioned articles of wealth, to offer in exchange for them. Partial gluts, occasioned by the one or the other of these causes, are among the most ordinary commercial occurrences. But the opinion to which our doctrine is opposed is that which admits the possibility not only of partial but of *universal* gluts, which supposes it possible that there may be at the same time a glut of services and commodities in general, —that we may have too much of every thing; a doctrine not only of frequent occurrence in conversations on commercial subjects, but even maintained by some distinguished writers. Now as by the assumed hypothesis of a universal glut all the articles of wealth exist not only in abundance, but in superabundance, an absolute deficiency of equivalents cannot be one of its causes. And it can scarcely be supposed that there can be such a general state of commercial cross-purposes as to prevent, in the majority of cases, the proper sellers and purchasers from meeting. It can scarcely be supposed that when A has what B wants, and B what A wants, A and B should, in the majority of instances, instead of finding out and exchanging with one another, offer their respective commodities to Y and Z, who, having also each reciprocal wants and supplies, neither wish to purchase from A or B, nor have discovered the means of exchanging with one another. But if it be absurd to suppose that a general glut could be occasioned by such an universal spirit of blundering as this, the only remaining hypothesis on which the existence of a general glut can be supposed is that of a general satiety, that all men may be so fully provided with the precise articles which they desire as to afford no market for each other's superfluities. And this doctrine is opposed to the proposition with which we set out, that every man desires to obtain additional wealth.

Population.

Population.

Having explained the sense in which we use the word wealth, and stated, or rather recalled to the recollection of our readers, the general desire to obtain additional wealth with the least possible sacrifice, we now proceed to consider the second of the four elementary propositions on which the Science of Political Economy is founded; namely, that the population of the world, or, in other words, the number of persons inhabiting it, is limited only by moral or physical evil, or by fear of the deficiency of those articles of wealth which the habits of the individuals of each class of its inhabitants lead them to require.

It is now generally admitted, indeed it is strange that it should ever have required to be pointed out, that every species of plant or animal which is capable of increase, either by generation or by seed, must be capable of a constantly increasing increase; every addition to its numbers being capable of affording a source of still further additions; or, in other words, that wherever there is a capacity of increase, it must be a capacity of increase not by mere addition but by multiplication; or, to use the short form in which the proposition is usually stated, not in an arithmetical, but in a geometrical ratio. The rate at which any species of plant or animal is capable of increasing must depend on the average power of reproduction and the average period of existence of the individuals of which it is constituted. Wheat, we know, is an annual, and its average power of reproduction, perhaps, about six for one; on that supposition, the produce of a single acre might cover the globe in fourteen years. The rate at which the human race is capable of increasing has been determined by observation. It has been ascertained that, for considerable periods and in extensive districts, under temperate climates, it has doubled every twenty-five years.

The power of reproduction in the human race must, under similar climates, be always the same. We say, under similar climates, because the acceleration of puberty, which has been sometimes observed in tropical climates, unless checked, as is probably the case by an earlier cessation of child-bearing, would occasion increased fecundity. Now, the United States of America, the districts in which the rate of increase which we have mentioned has been most clearly ascertained, are not remarkable for the longevity of their inhabitants. We may infer, therefore, that such is the average power of reproduction and average duration of life in the individuals constituting the human species, that their number may double every twenty-five years. At this rate the inhabitants of every Country would, in the course of every five centuries, increase to above a million times their previous number. At this rate the population of England would, in five hundred years, exceed fifteen million millions: a population which would not allow them standing room. Such being the human powers of increase, the question is, by what checks is their expansion controlled? How comes it that the population of the world, instead of being now a million times as great as it was five hundred years ago, apparently has not doubled within that time, and certainly has not quadrupled?

Mr. Malthus has divided the checks to population into the preventive and the positive. The first are those which limit fecundity, the second those which decrease longevity. The first diminish the number of births, the second increase that of deaths. And as fecundity and longevity are the only elements of the calculation, it is clear that Mr. Malthus's division is exhaustive. The positive check to population is physical evil. The preventive checks are promiscuous intercourse and abstinence from marriage. The first is moral evil; the second is, with a very few exceptions, so few indeed that they do not affect the result, founded on an apprehended deficiency of some of the things to which we have given the general appellation of wealth. All the preventive and positive checks may therefore be distributed under prudence, moral evil, and physical evil. We will first consider the positive check.

We have seen that this check includes all the causes which tend, in any way, prematurely to shorten the duration of human existence: such as unwholesome occupations, severe labour, or exposure to the seasons, bad or insufficient food or clothing, bad nursing of children, excesses of all kinds, the corruption of the air from natural causes, or from large towns, wars, infanticide, plague, and famine. Of these, some arise from the laws of nature, and others from the crimes and follies of man: all are directly and immediately felt in the form of physical evil, though many of them are the result, more or less remotely, of moral evil.

The final and irresistible mode in which physical evil operates is the want of the necessaries of existence: death produced by hardship or starvation. This is almost the only check to the increase of the irrational animals, and as man descends towards their condition he falls more and more under its influence. In the lowest savage state it is the principal and obvious check; in a high state of civilization it is almost imperceptible; but is unperceived only in consequence of the operation of its substitutes.

We have already stated that, as a general rule, additional labour employed in the cultivation of the land within a given district produces a less proportionate return. And it has appeared that such is the power of reproduction and duration of life in mankind, that the population of a given district is capable of doubling itself at least every twenty-five years. It is clear, therefore, that the rate at which the production of food is capable of being increased, and that at which population, if unchecked, would increase, are totally different. Every addition made to the quantity of food periodically produced makes in general a further periodical addition more difficult. Every addition to the existing population diffuses wider the means of still further addition. If neither evil, nor the fear of evil, checked the population of England, it would amount in a century to above two hundred millions. Suppose it possible that we might be able to raise or to import the subsistence of two hundred millions of people: is it possible that one hundred and twenty-five years hence we should be able to support four hundred millions? or, in one hundred and fifty years, eight hundred millions? It is clear, however, that long before the first century had elapsed, long before the period at which, if unchecked, we should have attained two hundred millions, no excellence in our institutions, or salubrity of climate, or unremitting industry, could have saved us from being arrested in our progress by a constantly increasing want of subsistence. If all other moral and physical checks could be got rid of, if we had neither wars nor libertinism, if our habitations, and employments, and habits were all wholesome, and no fears of indigence or loss of station prevented or retarded our marriages, famine would soon exercise her prerogative of controlling, in the last resort, the multiplication of mankind.

But though it be certain that the absence of all other checks would only give room for the irresistible influence of famine, it is equally certain that such a state of things never has existed and never will exist.

In the first place the absence of all the other moral and physical evils which retard population implies a degree of civilization not only high, but higher than mankind have as yet enjoyed. Such a society cannot be supposed to want sagacity sufficient to foresee the evils of a too rapidly increasing population, and prudence sufficient to avoid them. In such a state the preventive check would be in full operation, and its force is quite sufficient to render unnecessary even the approach of any positive check.

And, secondly, it is impossible that a positive check, so goading and so remorseless as famine, should prevail without bringing in her train all the others. Pestilence is her uniform companion, and murder and war are her followers. Whole bodies of men will not tamely lie down to die, and witness, while they are perishing, their wives, and children, and parents, starving around them. Where there is a diversity of fortunes, famine generally produces that worst form of civil war, the insurrection of the poor against the rich. Among uncivilized nations it produces those tremendous hostile migrations in which a whole people throws itself across a neighbouring frontier, and either perishes in the attempt to obtain a larger or a more fertile territory, or destroys the former possessors, or drives them out to be themselves aggressors in turn.

In fact, almost all the positive checks, by their mutual reaction, have a tendency to create and aggravate one another; and the destruction of those who perish immediately by one may generally be found to have been remotely occasioned or promoted by one or more of the others. Among nations imperfectly civilized the widest and the most wasting of the positive checks is predatory war. A district exposed to it is likely to suffer all the others. Mere fear of invasion must generally keep the great body of its inhabitants pent up in crowded and consequently unwholesome towns; it must confine their cultivation to the fields in the immediate neighbourhood of those towns, and, if it does not destroy, must so much impede their commerce as to render it useless as a source of subsistence; and when the invasion does come, it is often followed by the complete extirpation of the invaded community. This is the check which has kept Africa, and the central parts of Asia, in their comparatively unpeopled state.

In his journey from Abyssinia to Sennaar, Bruce crossed the territory of Atbara, subject to the incursions of the Daveina Arabs. The whole seems to have been a scene of desolation. He passed a night at Garigara, a village, of which they had destroyed the crops a year before. The inhabitants had all perished with hunger, and their remains were unburied and scattered over the ground where the village had stood. The travellers encamped among the bones: no space could be found free from them. His next stage was Teawa. "Its consequence," he observes, "was to remain only till the Daveina should resolve to attack it, when its corn fields being burnt and destroyed in a night by a multitude of horsemen, the bones of its inhabitants scattered upon the earth would be all its remains, like those of the miserable village of Garigara."

Among the positive checks to the population of uncivilized, or partially civilized, nations, the next in importance to war is famine. When a people depends principally on that subsistence which is most easily obtained, and such is the case among the nations in question, the mere variations of the seasons must, from time to time, produce destructive want. Where society is better constituted, the evil of these variations is mitigated, partly from the superfluity of the more opulent classes, partly by importation, and principally by a recurrence to a less expensive diet; but in a barbarous, and consequently a poor and non-commercial people, they are among the most frighful forms of national calamity. The histories which we possess of such Countries always particularize periods of dearth as among the most memorable events recorded. They seem in a constant oscillation between the want endured by a population that has increased to the utmost limits of subsistence, and the plenty enjoyed by the survivors after that population has been thinned by war, pestilence, or famine. The remainder of the positive checks, such as infanticide and unwholesomeness of climate, habits, or situation, appear rather to facilitate early marriages than to produce any actual diminution, or prevent any actual increase of population. Infanticide has been supposed to be rather favourable to population, by opposing to the prudential check to marriage a mode of disposing of its offspring, which may appear easy in contemplation, but from which the feelings of the parents eventually recoil. The unwholesomeness of some districts is unquestionably such as to keep them totally unpeopled, or inhabited by strangers, whose numbers must be constantly recruited. Such, for instance, appears to be the case in the most unhealthy parts of Italy. Such is the case with large manufacturing towns even in the most favourable climates, unless great skill and great care are directed towards their cleanliness and ventilation. And in a newly colonized Country like the back settlements of America, where the abundance of land and the constantly increasing means of subsistence would render any preventive check unnecessary, any cause diminishing longevity must retard increase. But with these exceptions, unhealthiness rather causes the successive generations to pass more rapidly away, than diminishes the actual number of inhabitants. In some of the healthiest districts of Swisserland the average annual mortality does not exceed one in forty-eight. In many of the marshy villages of Holland it exceeds one in twenty-three. But it would be rash to expect the population of the former to be more dense or to increase more rapidly than that of the latter. The case is, in fact, the reverse. In the Swiss villages of which we have been speaking the births are as rare as the deaths; the population is thin and stationary. Among the Dutch the births somewhat exceed the deaths; the population is dense and is increasing. It is obvious, indeed, that the proportion of annual births to the whole number of people being given, the rate of increase must depend on the proportion borne by the annual deaths. And again, the proportion of deaths to the whole number of people being given, it must depend on the proportion borne by the births; or, to use a shorter form of expression, given the longevity it must depend on the fecundity, and given the fecundity it must depend on the longevity. If both are given, the rate of increase may be calculated; but from only one, the conclusion must be in the disjunctive. If the annual births bear a large proportion to the existing number of people, we may conclude either that the population is rapidly increasing, or that the positive checks are in powerful operation. On the other hand, from a small proportion of annual deaths may be inferred either a rapid increase of numbers, or a strong influence of the preventive checks. The average duration of life in England is greater than in the United States of America; but so much greater is the force of the preventive checks, that the rate of increase in America is about double that in England. Again, the average duration of life in the Swiss villages to which we have referred is the same as it is in England; but the preventive check in England, strong as it appears when compared with its force in America, is so much weaker than it is in some districts in Swisserland, that, with the same annual mortality, the population is in the one Country stationary, in the other rapidly progressive.

But although the average longevity in a Country affords no decisive evidence as to the increasing or stationary number of its inhabitants, it is among the least deceitful tests of their prosperity; far less so than that on which legislators formerly relied, the number of births. There is not an evil, moral or physical, which has not a tendency, directly or indirectly, to shorten life, but there are many which have a direct tendency to increase fecundity. The extraordinary duration of life in Great Britain, exceeding, as it does, the average of any other equally populous district, is a convincing proof of the general excellence of our climate, our institutions, and our habits.

We now proceed to consider the preventive checks to the increase of population. We have seen that they are promiscuous intercourse and abstinence from marriage.

The first does not appear to be of sufficient importance to require much consideration. It is said to produce some effect in checking the increase of the higher classes in some of the South Sea Islands; and it appears to have produced the same effect to a considerable extent among the West Indian negroes. But the nobility of the South Seas scarcely deserve to be separately considered. And, while the other forms of moral and physical evil were accumulated, as they were among the West Indian slaves, it is probable that the removal of this evil alone would have done little to promote the increase of their population.

But, with these exceptions, there are scarcely any females whose fecundity is prevented or diminished by promiscuous intercourse, except those unhappy individuals whose only trade is prostitution. And they form so small a proportion of the population of the whole world that the check to population, occasioned by their unfruitfulness, may safely be disregarded.

The only remaining check is abstinence from marriage. Our readers are of course aware that, by the word "marriage," we mean to express not the peculiar and permanent connection which alone, in a Christian Country, is entitled to that name, but any agreement between a man and woman to cohabit under circumstances likely to occasion the birth of progeny. We have already observed that abstinence from marriage is almost uniformly founded on the apprehension of a deficiency of some of the things which we have denominated by the general term wealth, or, in other words, on prudence. Some cases certainly occur in which men remain unmarried, although their fortunes are so ample that the expenses of a family would be unperceived. But the number of persons so situated is so small that they create an exception which would scarcely deserve attention, even if this conduct were as common among them as it is, in fact, rare.

We shall scarcely, therefore, be led into error if, in considering the preventive checks, we confine our attention to prudence, and assume that, as nothing but physical evil directly and immediately diminishes the longevity of mankind, nothing but an apprehended deficiency of some of the articles of wealth prevents their fecundity.

But though an apprehended deficiency of some of the articles of wealth is substantially the only preventive check to the increase of population, it is obvious that fear of the want of different articles operates, with all men, very differently; and even that an apprehended want of the same article will affect differently the minds of the individuals of different classes. An apprehended want of corn would produce on the minds of all Englishmen a very different effect from an apprehended want of silk. An apprehended want of butcher's meat would affect very differently the minds of Englishmen of different classes. It appears to us, therefore, convenient to divide for this purpose the articles of wealth into the three great classes of necessaries, decencies, and luxuries, and to explain the different effects produced by the fear of the want of the articles of wealth falling under each class. We must begin, however, by stating, as precisely as we can, what we mean by the words *necessaries, decencies, and luxuries;* terms which have been used ever since the Moral Sciences first attracted attention, but with little attention to precision or to consistent use.

It is scarcely necessary to remind our readers that these are relative terms, and that some person must always be assigned with reference to whom a given commodity or service is a luxury, a decency, or a necessary.

By *necessaries*, then, we express those things, the use of which is requisite to keep a given individual in the health and strength essential to his going through his habitual occupations.

By *decencies*, we express those things which a given individual must use in order to preserve his existing rank in society.

Every thing else of which a given individual makes use, or, in other words, all that portion of his consumption which is not essential to his health and strength, or to the preservation of his existing rank in society, we term *luxury*.

It is obvious that when consumed by the inhabitants of different Countries, or even by different individuals in the same Country, the same things may be either luxuries, decencies, or necessaries.

Shoes are necessaries to all the inhabitants of England. Our habits are such that there is not an individual whose health would not suffer from the want of them. To the lowest class of the inhabitants of Scotland they are luxuries: custom enables them to go barefoot without inconvenience and without degradation. When a Scotchman rises from the lowest to the middling classes of society, they become to him decencies. He wears them to preserve, not his feet, but his station in life. To the highest class, who have been accustomed to them from infancy, they are as much necessaries as they are to all classes in England. To the higher classes in Turkey wine is a luxury and tobacco a decency. In Europe it is the reverse. The Turk drinks and the European smokes, not in obedience, but in opposition both to the rules of health and to the forms of society. But wine in Europe and the pipe in Turkey are among the refreshments to which a guest is entitled, and which it would be as indecent to refuse in the one Country as to offer in the other.

It has been said that the coal-heavers and lightermen, and some others among the hardworking London labourers, could not support their toils without the stimulus of porter. If this be true, porter is to them a necessary. To all others it is a luxury. A carriage is a decency to a woman of fashion, a necessary to a physician, and a luxury to a tradesman.

The question, whether a given commodity is to be considered as a decency or a luxury, is obviously one to which no answer can be given, unless the place, the time, and the rank of the individual using it be specified. The dress which in England was only decent a hundred years ago, would be almost extravagant now, while the house and furniture which now would afford merely decent accommodation to a gentleman, would then have been luxurious for a Peer. The causes which entitle a commodity to be called a necessary are more permanent and more general. They depend partly upon the habits in which the individual in question has been brought up, partly on the nature of his occupation, on the lightness or the severity of the labours and hardships that he has to undergo, and partly on the climate in which he lives.

Of these causes we have illustrated the two first by the familiar examples of shoes and porter. But the principal cause is climate. The fuel, shelter, and raiment, which are essential to a Laplander's existence, would be worse than useless under the Tropics. And as habits and occupations are very slowly changed, and climate suffers scarcely any alteration, the commodities which are necessary to the different classes of the inhabitants of a given district may, and generally do, remain for centuries unchanged, while their decencies and luxuries are continually varying.

Among all classes the check imposed by an apprehended deficiency of mere luxuries is but slight. The motives, perhaps we might say the instincts, that prompt the human race to marriage, are too powerful to be much restrained by the fear of losing conveniences unconnected with health or station in society. Nor is population much retarded by the fear of wanting mere necessaries. In comparatively uncivilized Countries, in which alone, as we have already seen, that want is of familiar occurrence, the preventive check has little operation. They see the danger, but want prudence and self-denial to be influenced by it. On the other hand, among nations so far advanced in civilization as to be able to act on such a motive, the danger that any given person or his future family shall actually perish from indigence appears too remote to afford any general rule of conduct.

The great preventive check is the fear of losing decencies, or, what is nearly the same, the hope to acquire, by the accumulation of a longer celibacy, the means of purchasing the decencies which give a higher social rank. When an Englishman stands hesitating between love and prudence, a family actually starving is not among his terrors; against actual want he knows that he has the fence of the poor-laws. But, however humble his desires, he cannot contemplate without anxiety a probability that the income which supported his social rank, while single, may be insufficient to maintain it when he is married; that he may be unable to give to his children the advantages of education which he enjoyed himself; in short, that he may lose his caste. Men of more enterprise are induced to postpone marriage, not merely by the fear of sinking, but also by the hope that in an unincumbered state they may rise. As they mount the horizon of their ambition keeps receding, until sometimes the time has passed for realizing those plans of domestic happiness which probably every man has formed in his youth.

It is by this desire of decencies, as distinguished from necessaries, that long-settled civilized Countries are preserved from the evils of a population greatly exceeding the means of comfortable subsistence. There are few triter subjects of declamation than the contrast between ancient simplicity and modern luxury. Few virtues, however useful, have received more applause than the contented and dignified poverty, the indifference to display, and the abstinence from unnecessary expense, which all refined nations attribute to their ancestors. Few vices, however mischievous, have been more censured than the ostentatious expenditure which every succeeding generation seems to consider its own characteristic.

It certainly seems at first sight that habits of unnecessary expenditure, as they have a tendency to diminish the wealth of an individual, must have the same effect on the wealth of a nation. And, separately considered, it appears clear that each act of unproductive consumption, whatever gratification it may afford to the consumer, must, *pro tanto*, impoverish the community. It is so much taken from the common stock and destroyed. And as the national capital is formed from the aggregate savings of individuals, it is certain that if each individual were to expend to the utmost extent of his means, the whole capital of the Country would be gradually wasted away, and general misery would be the result. But it appears equally certain that if each individual were to confine his expenditure to mere necessaries, the result would be misery quite as general and as intense.

We have seen that the powers of population, if not restrained by prudence, must inevitably produce almost every form of moral and physical evil. In the case which we are supposing, the wants of society would be confined to the food, raiment, and shelter essential to the support of existence; and they would all consist of the cheapest materials. At present, among civilized nations, the cultivation of the land employs only a portion of its inhabitants, and, generally speaking, as a nation increases in wealth, a smaller and smaller proportion; in England not one third; and a great part of the labourers so employed are producers of luxuries. Indeed, as potatoes afford a food five or six times as abundant as corn, and more than twenty times as abundant as meat, and, as far as can be judged by the appearance and powers of the lower Irish, quite as wholesome, meat and corn may be considered luxuries, to the extent in which they are more expensive than potatoes. Nor, consistently with the existence of private property, and of the desire of wealth, can the mode of cultivation be directed to the obtaining the largest possible return. The object is to obtain the largest return that is consistent with profitable farming, but, in the pursuit of this object, quantity of produce must often be sacrificed to economy of labour or time.

If there were no desire for any thing beyond necessaries, both the existing partition of the land, and the existing division of labour, would be varied. No family would wish to occupy more land than the small plot necessary to afford them potatoes and milk. Supposing them to give to it the utmost nicety of garden cultivation, its management would still leave them time to produce the coarse manufactures necessary for their own use. The whole of the population would be agricultural. 761,348 families so employed at present in England, although their labour is far from being directed to the production of the greatest possible amount, provide, without much assistance from importation, subsistence for the whole of our 2,745,336 families. If all were so employed, and if quantity of produce were their sole object, it is probable that in ordinary seasons the soil of England, instead of fifteen millions, could feed at least sixty millions of people; and that of Europe, instead of two hundred, eight hundred millions. And that, in the absence of any checks more powerful than those experienced in the United States of America, the population of Europe might in fifty years amount to eight hundred millions. Indeed it is probable that, under the circumstances which we are supposing, the increase in Europe would be for a considerable time rather more rapid than that which has taken place in America. Preventive checks would not exist; marriages could not be hindered or even delayed by prudence, since there could be no reason to anticipate want; the habit of early marriages would put an end to profligacy; and, as all our habits would be eminently healthy, the positive checks would be reduced to their minimum.

So far the picture is rather pleasing; it exhibits a state of society, not rich certainly, nor refined, but supporting a very numerous population in health and strength, and in the full enjoyment of the many sources of happiness connected with early marriage. But it is obvious that this could not last for ever; it could not last indeed for two hundred and fifty years. By that time the population of Europe would amount to above three million millions; a number which the wildest imagination cannot conceive capable of existing simultaneously in the whole earth.

Sooner or later, therefore, the increase must be checked; and we have seen that prudence is the only check that does not involve vice or misery. But such is the force of the passions which prompt to marriage, and such is each man's reliance on his own good conduct and good fortune, that the evils, whatever they may be, the apprehension of which forms the prudential check, are frequently incurred. Where that evil is the loss of luxuries, or even of decencies, it is trifling in the first case, and bearable in the second. But, in the case which we are supposing, the only prudential check would be an apprehended deficiency of necessaries; and that deficiency, in the many instances in which it would actually be incurred, would be the positive check in its most frightful form. It would be incurred not only in consequence of that miscalculation of chances to which all men are subject, and certainly those not the least so who are anxious to marry, but through accidents against which no human prudence can guard. A *single* bad harvest may be provided against, but a succession of unfavourable seasons (and such successions do occur) must reduce such a people to absolute famine. When such seasons affect a nation indulging in considerable superfluous expenditure, they are relieved by a temporary sacrifice of that superfluity. The grain consumed in ordinary years by our breweries and distilleries is a store always at hand to supply a scarcity, and the same may be said of the large quantity of food raised for the support of domestic animals, but applicable to human subsistence. To these resources may be added the importation from abroad of necessaries instead of luxuries and the materials of luxury, of corn, for instance, instead of wine.

It may be said however, and indeed it has been said, that while the globe remains in its present irregularly occupied and irregularly cultivated state, emigration affords to all comparatively thickly-peopled nations a resource so ample and so easy as to render every prudential check to population unnecessary.

It is obvious that if capital and skill equal to those bestowed on the best parts of Flanders, or of the Scotch Lowlands, could be applied to the whole habitable world, a population ten times, perhaps one hundred times, perhaps even five hundred times as large could be maintained, as well, perhaps far better, than the one thousand millions now supposed to exist on its surface. It is possible, we will not say even that it is improbable, that in the course of centuries, or rather of hundreds of centuries, these splendid visions may be realized. But all experience shows that no numerous and civilized nation, surrounded by other civilized nations, can venture to rely on emigration as a permanent and adequate check to population. We say no numerous and civilized nation surrounded by other civilized nations; for we are aware that the hordes of Central Asia and of the Northern parts of Europe, and the surplus inhabitants of some small communities, such as the petty States of ancient Greece and Phœnicia, appear to have found, the one in colonization, the others in armed migrations, a periodical outlet; and that the Americans of European descent have enjoyed for centuries, and for centuries to come may enjoy, in the immense continent behind them, room for as rapid an increase of their numbers as the most unchecked propagation can supply. But these are not examples which Europe, as now constituted, can imitate. When all the land frontier is appropriated,—when invasion for the purpose of settlement is impossible, and the solitary traveller is repelled by a different language, different laws, different arts, and often a different religion,—when the other alternative is an expensive and distant voyage, and either an unsettled, and therefore in general an unwholesome country, or equal obstacles from variations of laws, language, religion, and arts, in a previously settled district,—when these are the difficulties to be encountered, no extensive and systematic emigration will be persisted in. Even the different parts of the same empire afford little assistance to one another, if difference of language, or habits, or considerable distance be interposed. The Austrian dominions contain some of the most thinly and some of the most thickly peopled portions of Europe; but Hungary is not colonized from the plains of Lombardy. If any European nation could hope to make emigration a complete substitute for prudence, that hope might be entertained by the inhabitants of the British Islands. We have the command of unoccupied continents in each hemisphere, the largest navy that the world ever saw to convey us to them, the largest capital that ever has been accumulated to defray the expense, and a population remarkable not merely for enterprise, but for enterprise of this particular description. These advantages we have enjoyed for centuries; almost from the times of the Tudors we have possessed a large outskirt of empire far exceeding in extent our European possessions. And yet during this long period how little effect has emigration produced on our numbers! The swarms which we have sent out, and which we now send out, seem to be instantaneously replaced. We have founded one empire, and probably shall found many; but, after once a colony has been planted, its principal increase arises, not from the comparatively scanty recruits whom it receives from home, but from the unrepressed force of human fecundity.

In a future portion of this Treatise we shall explain with more detail the causes which impede emigration; at present we shall only repeat that all experience shows its inability to keep down the population of any large, well peopled, and tolerably civilized Country, such as Europe, China, or Hindostan. It appears, therefore, that habits of prudence in contracting marriage, and of considerable superfluous expenditure, afford the only permanent protection against a population pressing so closely on the means of subsistence as to be continually incurring the misery of the positive checks. And as the former habits exist only in a civilized, and the latter only in an opulent society, it appears equally clear that, as a nation advances in civilization and opulence, the positive checks are likely to be superseded by the preventive. If this be true, the evil of a redundant population, or, to speak more intelligibly, of a population too numerous to be adequately and regularly supplied with necessaries, is likely to diminish in the progress of improvement. As wealth increases, what were the luxuries of one generation become the decencies of their successors. Not only a taste for additional comfort and convenience, but a feeling of degradation in their absence, becomes more and more widely diffused. The increase in many respects of the productive powers of labour must enable increased comforts to be enjoyed by increased numbers: and as it is the more beneficial, so it appears to be the more natural course of events that increased comfort should not only accompany but rather precede increase of numbers.

But although we believe that, as civilization advances, the pressure of population on subsistence is a decreasing evil, we are far from denying the prevalence of this pressure in all long-settled Countries; indeed in all Countries except those which are the seats of colonies applying the knowledge of an old Country to an unoccupied territory. We believe that there are few portions of Europe the inhabitants of which would not now be richer if their numbers were fewer, and would not be richer hereafter if they were now to retard the rate at which their population is increasing. No plan for social improvement can be complete unless it embrace the means both of increasing the production of wealth and of preventing population from making a proportionate advance. The former is to be effected by legislative, the latter by individual prudence and forethought. The former must be brought about by the governing classes of society; the latter depends almost entirely on the lower. As a means of improvement, the latter is, on the whole, more efficient. It may be acted upon or neglected by almost every one. But, in the present state of public opinion and of commercial and fiscal policy in Europe, perhaps a greater progress may be made by insisting on the former. The statesman who neglects either considers only a portion of the subject.

But we must admit that ours are not the received opinions; or perhaps we ought to say, that our statement is opposed, on the one side or on the other, to the language used by almost every writer who has directly treated the subject of population. Almost every Economist will be found, in that part of his writings in which what has been called *the principle of population* is the immediate and principal question considered, to range himself under one of two hostile banners, each opposed not only to the other, but also to the doctrines which we have endeavoured to explain. On one side are those who believe that an increase of numbers is necessarily accompanied not merely by a positive, but by a relative increase of productive power; that density of population is the cause and the test of prosperity; and that, "were every nation under the sun to be released from all the natural and artificial checks on their increase, and to start off breeding at the fastest possible rate, many, very many generations must elapse before any necessary pressure could be felt." *

On the other side are those who maintain that population has a tendency (using the word tendency to express likelihood or probability) to increase beyond the means of subsistence; or, in other words, that, whatever be the existing means of subsistence, population is likely fully to come up to them, and even to struggle to pass beyond them, and is kept back principally by the vice and misery which that struggle must produce.

The whole of our previous remarks afford an answer to the first mentioned class of writers. We shall not therefore recur to them. The opinions of the other class we shall consider at some length: and we will begin by the following quotations from Mr. M'Culloch, Mr. Mill, and Mr. Malthus.

Among the valuable notes which Mr. M'Culloch has appended to his edition of the *Wealth of Nations*, one of the most interesting treats of population; and one of the objects of that note is to show that the population of the United States of America cannot continue to increase for any very considerable period at the rate at which it has increased during the last hundred years. We are perfectly convinced of the correctness of this anticipation; and we make the following extract not with any intention to oppose Mr. M'Culloch's opinions as to America, but because we are anxious to express our dissent to the form in which he lays down the general doctrine of population.

"It may be said perhaps," says Mr. M'Culloch, "that allowance must be made for the effects of the improvements which may be supposed to take place in agricultural science in the progress of society, or the possible introduction, at some future period, of new and more prolific species of crops. But it is easy to see that the influence of such improvements and changes must, supposing them to be realized in the fullest manner, be of very temporary duration; and that it cannot affect the truth of the principle, *that the power of increase in the human species must always, in the long run, prove an overmatch for the increase in the means of subsistence.* Suppose by some extraordinary improvement the quantity of food and other articles required for the subsistence and accommodation of man annually produced in Great Britain were suddenly doubled; the condition of all classes being in consequence signally improved, there would be less occasion for the exercise of moral restraint; the period of marriage would therefore be accelerated, and such a powerful stimulus would be given to the principle of increase, *that in a very short period the population would be again on a level with the means of subsistence;* and there would also, owing to the change that must have been made in the habits of the people with respect to marriage, during the period that the population was rising to the level of the increased supply of food, be an extreme risk lest it should become too abundant, and produce an increased rate of mortality. Although, therefore, it is not possible to assign any certain limits to the progress of improvement, it is notwithstanding evident that it cannot continue for any considerable period to advance in the same proportion that population would advance supposing food were abundantly supplied. The circumstance of inferior lands, which require a greater outlay of capital and labour to make them yield the same supply as those that are superior, being invariably taken into cultivation in the progress of society, demonstrates, what is otherwise indeed sufficiently obvious to every one, that, in despite of improvements, the difficulty of adding to the supplies of food is progressively augmented as population becomes denser."

---

* Scrope, *Principles of Political Economy*, 1833, p. 276.

Mr. Mill's views are to be found in his discussion of wages. *Principles*, &c., ch. ii. s. 2. "If it were," he observes, "the natural tendency of capital (by which term Mr. Mill designates the instruments of labour, the materials on which they are to be employed, when produced by labour, and the subsistence of the labourer) to increase faster than population, there would be no difficulty in preserving the prosperous condition of the people. If, on the other hand, it were the natural tendency of population to increase faster than capital, the difficulty would be very great. There would be a perpetual tendency in wages to fall; the progressive fall of wages would produce a greater and a greater degree of poverty among the people, attended with its inevitable consequences, misery and vice. As poverty, and its consequent misery, increased, mortality would also increase: of a numerous family born, a certain number only, from want of the means of well being, would be reared. By whatever proportion the population tended to increase faster than capital, such a proportion of those who were born would die; the ratio of increase in capital and population would then remain the same, and the fall of wages would proceed no further. That population *has* a tendency to increase faster than, in most places, capital has actually increased, is proved incontestably by the condition of the population in most parts of the globe. In almost all Countries the condition of the great body of the people is poor and miserable. This would have been impossible, if capital had increased faster than population. In that case wages must have risen; and high wages would have placed the labourer above the miseries of want. This general misery of mankind is a fact which can be accounted for upon one only of two suppositions: either that there is a natural tendency in population to increase faster than capital, or that capital has, by some means, been prevented from increasing so fast as it has a tendency to increase. This, therefore, is an inquiry of the highest importance."

As the result of that inquiry, Mr. Mill decides the second alternative in the negative; and consequently conceives himself to have established the former, namely, that there is a natural tendency in population to increase faster than capital.

Mr. Malthus's opinions appear to have been considerably modified during the course of his long and brilliant philosophical career. In the first edition of his great Work the principle of population was represented as an insurmountable obstacle to the permanent welfare of the mass of mankind. And even in the last edition the following passages are open to the same construction

"There are few States in which there is not a constant effort in the population to increase beyond the means of subsistence. This constant effort as constantly tends to subject the lower classes of society to distress, and to prevent any great permanent amelioration of their condition. These effects, in the present state of society, seem to be produced in the following manner:—We will suppose the means of subsistence in any Country to be just equal to the easy support of its inhabitants. The constant effort towards population, which is found to act even in the most vicious societies, increases the number of people before the means of subsistence are increased. The food, therefore, which before supported eleven millions, must now be divided between eleven millions and a half. The poor consequently must live much worse, and many of them be reduced to severe distress. The number of labourers also being above the proportion of work in the market, the price of labour must tend to fall, while the price of provisions would at the same time tend to rise. The labourer therefore must do more work to earn the same as he did before. During this season of distress the discouragements to marriage and the difficulty of rearing a family are so great that the progress of population is retarded. In the mean time, the cheapness of labour, the plenty of labourers, and the necessity of an increased industry amongst them, encourage cultivators to employ more labour upon their land, to turn up fresh soil, and to manure and improve more completely what is already in tillage, till ultimately the means of subsistence may become in the same proportion to the population as at the period from which we set out. The situation of the labourer being then again tolerably comfortable, the restraints to population are in some degree loosened; and after a short period the same retrograde and progressive movements, with respect to happiness, are repeated." *Population*, book i. chap. 2. "According to the principle of population, the human race *has a tendency* to increase faster than food. It has, therefore, *a constant tendency* to people a Country fully up to the limits of subsistence; meaning, by these limits, the lowest quantity of food which will maintain a stationary population." Book iii. chap. i. note.

But when the opposite doctrine, namely, that, in the absence of disturbing causes, subsistence is likely to increase more rapidly than population, was brought before him by Mr. Senior, he appears to have disavowed, we will not say his former expressions, but the inferences to which they lead.

"The meaning," says Mr. Malthus, "which I intended to convey by the expression to which you object" (that population has a tendency to increase faster than food) "was, that population was always ready and inclined to increase faster than food, if the checks which repressed it were removed; and that though these checks might be such as to prevent population from advancing upon subsistence, or even to keep it at a greater distance behind, yet that, whether population were actually increasing faster than food, or food faster than population, it was true that, except in new colonies, favourably circumstanced, population was always pressing against food, and was always ready to start off at a faster rate than that at which the food was actually increasing."

"We are quite agreed that, in the capacity of reason and forethought, man is endowed with a power naturally calculated to mitigate the evils occasioned by the pressure of population against food. We are further agreed that, in the progress of society, as education and knowledge are extended, the probability is that these evils will practically be mitigated, and the condition of the labouring classes be improved."*

So explained, Mr. Malthus's opinions are opposed to the expressions of Mr. Mill and Mr. M'Culloch; his admission that, "in the progress of society, the probability is that the evils occasioned by the pressure of population against food will be mitigated," is opposed to Mr. M'Culloch's statement, "that the power of increase in the human species must always in the long run prove an overmatch for the increase in the means of subsistence;" and to Mr. Mill's, "that the tendency of population to increase faster than, in most places, capital has actually increased, is proved incontestably by the condition of the population in most parts of the globe." Archbishop Whately, with his usual acuteness, has in the following passage traced the question to a verbal ambiguity.

"The doctrine, that, since there is a tendency in population to increase faster than the means of subsistence, hence the pressure of population against subsistence may be expected to become greater and greater in each successive generation, (unless new and extraordinary remedies are resorted to,) and thus to produce a progressive diminution of human welfare—this doctrine, which some maintain in defiance of the fact that all civilized Countries have a greater proportionate amount of wealth now than formerly, may be traced chiefly to an undetected ambiguity in the word 'tendency,' which forms a part of the middle term of the argument. By a 'tendency' towards a certain result is sometimes meant, the existence of a cause which, operating unimpeded, would produce that result. In this sense it may be said, with truth, that the earth, or any other body moving round a centre, has a tendency to fly off at a tangent; (*i. e.*) the centrifugal force operates in that direction, though it is controlled by the centripetal; or, again, that man has a greater tendency to fall prostrate than to stand erect; (*i. e.*) the attraction of gravitation and the position of the centre of gravity are such that the least breath of air would overset him, but for the voluntary exertion of muscular force: and, again, that population has a tendency to increase beyond subsistence; (*i. e.*) there are in man propensities which, if unrestrained, lead to that result.

"But sometimes, again, 'a tendency towards a certain result' is understood to mean 'the existence of such a state of things that that result may be expected to take place.' Now it is in these two senses that the word is used, in the two premises of the argument in question. But in this latter sense, the earth has a greater tendency to remain in its orbit than to fly off from it; man has a greater tendency to stand erect than to fall prostrate; and (as may be proved by comparing a more barbarous with a more civilized period in the history of any Country) in the progress of Society, subsistence has a tendency to increase at a greater rate than population. In this Country, for instance, much as our population has increased within the last five centuries, it yet bears a far less ratio to subsistence (though still a much greater than could be wished) than it did five hundred years ago."*

It is obvious that if the present state of the world, compared with its state at our earliest records, be one of relative poverty, the tendency of population to increase more rapidly than subsistence must be admitted. If the means of subsistence continue to bear precisely the same proportion to the number of its inhabitants, it is clear that the increase of subsistence and of numbers has been equal. If its means of subsistence have increased much more than the number of its inhabitants, it is clear not only that the proposition in question is false, but that the contrary proposition is true, and that the means of subsistence have a natural tendency (using these words as expressing what is likely to take place) to increase faster than population. Now what is the picture presented by the earliest records of those nations which are now civilized, or, which is the same, what is now the state of savage nations?—a state of habitual poverty and occasional famine. A scanty population, but still scantier means of subsistence. Admitting, and it must be admitted, that in almost all Countries the condition of the great body of the people is poor and miserable, yet, as poverty and misery were their original inheritance, what inference can we draw from the continuance of that misery as to the tendency of their numbers to increase more rapidly than their wealth? But if a single Country can be found in which there is now less poverty than is universal in a savage state, it must be true that, under the circumstances in which that Country has been placed, the means of subsistence have a greater tendency to increase than the population. Now this is the case in every civilized Country. Even Ireland, the Country most likely to afford an instance of what has been called the tendency of things, poor and populous as she is, suffers less from want with her eight millions of people than when her only inhabitants were a few septs of hunters and fishers. In our own early history, famines, and pestilences, the consequences of famine, constantly recur. At present, though our numbers are trebled or quadrupled, they are unheard of.

The United States of America afford the best ascertained instance of great and continued increase of numbers. They have afforded a field in which the powers of population have been allowed to exhaust their energy; but, though exerted to their utmost, they have not as yet equalled the progress of subsistence. Whole colonies of the first settlers perished from absolute want; their successors struggled long against hardship and privation; but every increase of their number seems to have been accompanied or preceded by increased means of support. If it be conceded that there exists in the human race a natural tendency to advance from barbarism to civilization, and that the means of subsistence are proportionably more abundant in a civilized than in a savage state, and neither of these propositions can be denied, it must follow that there is a natural tendency in subsistence to increase in a greater ratio than population.

* *Appendix to* Senior's *Lectures on Population*, p. 61—82.

* Archbishop Whately, *Lectures on Political Economy. Lecture* 9.

But although Mr. Malthus himself, in his earlier publications, has perhaps fallen sometimes into the exaggeration which is natural to a discoverer, the error, if he has committed one, does not affect the practical conclusions which place him, as a benefactor to mankind, on a level with Adam Smith. Whether, in the absence of disturbing causes, it be the tendency of subsistence or of population to advance with greater rapidity, is a question of slight importance, if it be acknowledged that human happiness or misery depend principally on their relative advance, and that there are causes, and causes within human control, by which that advance can be regulated. These are propositions which Mr. Malthus has established by facts and reasoning which, opposed as they were to long-rooted prejudice, and assailed by every species of sophistry and clamour, are now admitted by the majority of reasoners, and even by a large majority of those who take their opinions upon trust.

To explain what are the causes of the relative increase of subsistence and population is rather the business of a writer on politics than of a Political Economist. At present we will only say that knowledge, security of property, freedom of internal and external exchange, and equal admissibility to rank and power, are the principal causes which at the same time promote the increase of subsistence, and, by elevating the character of the people, lead them to keep at a slower rate the increase of their numbers. And that restrictions on exchange and commerce, artificial barriers excluding the great majority of the community from the chance of social eminence, and, above all, ignorance, and insecurity of person and property, are the general causes which both diminish the productiveness of labour, and tend to produce that brutal state of improvidence in which the power of increase, unchecked by prudence, is always struggling to pass the limits of subsistence, and is kept down only by vice and misery. We use the expression *general* causes, to exclude those causes which, being peculiar to certain nations, require separate consideration. Such are the superstitious desire of offspring in China, the political motives which formerly occasioned the creation of freeholders in Ireland, and the administration of the poor laws in some parts of England. But, omitting these details, it may be generally stated that all that degrades the character, or diminishes the productive power of a people, tends to diminish the proportion of subsistence to population, and *vice versâ*. And consequently that a population increasing more rapidly than the means of subsistence is, generally speaking, a symptom of misgovernment indicating deeper-seated evils, of which it is only one of the results.

And, notwithstanding the passages which we have cited, we believe these to be also the opinions of Mr. Mill and of Mr. M'Culloch. We believe that neither of these eminent writers doubts that the situation of the inhabitants of Europe has been gradually improving during the last 500 years. We believe that neither of them considers the improvement as having reached its limit, or as having any definite limit whatever. When they speak of the probable destinies of mankind, they teach the same doctrine as ourselves. It is only when separately discussing the subject of population that they have used the language to which we have ventured to object. We believe that they have used it without being misled by it themselves, and, perhaps on that very account, without perceiving its tendency to mislead others. But that those whose acquaintance with Political Economy is superficial (and they form the great mass of even the educated classes) *have* been misled by the form in which the doctrine of population has been expressed appears to us undeniable. When such persons are told that "it is the tendency of the human race to increase faster than food"—"to people a country fully up to the means of subsistence," they infer that what *has a tendency to happen* is to be expected. Because additional population *may* bring poverty, they suppose that it necessarily *will* do so: because increased means of subsistence *may* be followed and neutralized by a proportionate increase in the number of persons to be subsisted, they suppose that such *will* necessarily be the case. And unhappily there are many whom indolence, or selfishness, or a turn to despondency, make ready recipients of such a doctrine. It furnishes an easy escape from the trouble or expense implied by every project of improvement. "What use would it be," they ask, "to promote an extensive emigration? the whole vacuum would be immediately filled up by the necessary increase of population. Why should we alter the Corn Laws? If food were for a time more abundant, *in a very short period the population would be again on a level with the means of subsistence*, and we should be just as ill off as before."

There are many also, particularly among those who reason rather with their hearts than their heads, who are unable to assent to these doctrines, and yet believe them to be among the admitted results of Political Economy. Such persons apply to the whole Science the *argumentum ab absurdo*; and, instead of inquiring into the accuracy of the reasoning, refuse to examine the premises from which such objectionable conclusions are inferred.

It is because we believe these misconceptions to be extensively prevalent that we have ventured to detain our readers by this long discussion. A discussion which some may think a mere dispute about the more convenient use of a word, and others an attempt to prove a self-evident fact.

Production.

Having explained the sense in which we use the word wealth, and given an outline of the doctrine of population, we now proceed to consider production, or the means by which wealth is produced. The first terms to be defined are the verb *produce*, and the substantive *product*.

To produce, as far as Political Economy is concerned, *is to occasion an alteration in the condition of the existing particles of matter, for the occasioning of which alteration, or for the things thence resulting, something may be obtained in exchange.* This alteration is a *product*. It is scarcely necessary to remind our readers that matter is susceptible neither of increase nor diminution, and that all which man or any other agent of which we have experience can effect, is to alter the condition of its existing particles. But as Political Economy treats only of wealth, and therefore only of those alterations of which wealth is the result, we are forced to exclude all other alterations from the definition of products. The child who builds a castle with sand on the shore, and the child who kicks it down, each occasions effects the same in kind as the man who builds or pulls down a palace; but as the exertions of the latter entitle him to be paid, he is properly said to *produce*, and the result of his conduct, whether it be the covering with buildings ground previously unoccupied, or rendering vacant what was previously built over, is properly called a product.

Products have been divided into material and immaterial, or, to express the same distinction in different words, into commodities and services. This distinction appears to have been suggested by Adam Smith's well-known division of labour into productive and unproductive. Those who thought the principle of that division convenient, feeling at the same time the difficulty of terming unproductive the labour without which all other labour would be inefficient, invented the term services, or immaterial products, to express its results.

It appears to us, however, that the distinctions that have been attempted to be drawn between productive and unproductive labourers, or between the producers of material and immaterial products, or between commodities and services, rest on differences existing not in the things themselves, which are the objects considered, but in the modes in which they attract our attention. In those cases in which our attention is principally called not to the act of occasioning the alteration, but to the result of that act, to the thing altered, Economists have termed the person who occasioned that alteration a productive labourer, or the producer of a *commodity* or material product. Where, on the other hand, our attention is principally called not to the thing altered, but to the act of occasioning that alteration, Economists have termed the person occasioning that alteration an unproductive labourer, and his exertions, *services*, or immaterial products. A shoemaker alters leather and thread and wax into a pair of shoes. A shoeblack alters a dirty pair of shoes into a clean pair. In the first case our attention is called principally to the things as altered. The shoemaker, therefore, is said to *make* or *produce* shoes. In the case of the shoeblack, our attention is called principally to the act as performed. He is not said to make or produce the commodity, clean shoes, but to perform the service of cleaning them. In each case there is of course an act and a result; but in the one case our attention is called principally to the act, in the other to the result.

Among the causes which direct our attention principally to the *act*, or principally to the *result*, seem to be, first, the degree of change produced; and secondly, the mode in which the person who benefits by that change generally purchases that benefit.

1. Where the alteration is but slight, especially if the thing that has been subjected to alteration still retains the same name, our attention is directed principally to the act. A cook is not said to *make* roast beef, but to *dress* it; but he is said to make a pudding, or those more elaborate preparations which we call *made* dishes. The change of name is very material: a tailor is said to *make* cloth into a coat; a dyer is not said to *make* undyed cloth into dyed cloth. The change produced by the dyer is perhaps greater than that produced by the tailor, but the cloth in passing through the tailor's hands changes its name; in passing through the dyer's it does not: the dyer has not produced a *new name*, nor, consequently, in our minds, a *new thing*.

The principal circumstance, however, is the mode in which the payment is made. In some cases the producer is accustomed to sell, and we are accustomed to purchase, not his labour, but the subject on which that labour has been employed; as when we purchase a wig or a chest of medicine. In other cases, what we buy is not the thing altered, but the labour of altering it, as when we employ a haircutter or a physician. Our attention in all these cases naturally fixes itself on the thing which we are accustomed to purchase; and according as we are accustomed to buy the labour, or the thing on which that labour has been expended,—as we are, in fact, accustomed to purchase a commodity or a service, we consider a commodity or a service as the thing produced. The ultimate object both of painting and of acting is the pleasure derived from imitation. The means adopted by the painter and the actor are the same in kind. Each exercises his bodily organs, but the painter exercises them to distribute colours over a canvass, the actor to put himself into certain attitudes, and to utter certain sounds. The actor sells his exertions themselves. The painter sells not his exertions, but the picture on which those exertions have been employed. The mode in which their exertions are sold constitutes the only difference between menial servants and the other labouring classes: a servant who carries coal from the cellar to the drawing-room performs precisely the same operation as the miner who raises them from the bottom of the pit to its mouth. But the consumer pays for the coals themselves when raised and received into his cellar, and pays the servant for the act of bringing them up. The miner, therefore, is said to produce the material commodity, coals; the servant the immaterial product, or service. Both, in fact, produce the same thing, an alteration in the condition of the existing particles of matter; but our attention is fixed in the one case on the act, in the other on the result of that act.

In the ruder states of society almost all manufactures are domestic: the Queens and Princesses of heroic times were habitually employed in overlooking the labours of their maidens. The division of labour has banished from our halls to our manufactories the distaff and the loom; and, if the language to which we have been adverting were correct, the division of labour must be said to have turned spinners and weavers from unproductive into productive labourers; from producers of immaterial services into producers of material commodities.

But objecting as we do to a nomenclature which should consider producers as divided, by the nature of their products, into producers of services and producers of commodities, we are ready to admit the convenience of the distinction between services and commodities themselves, and to apply the term *service* to the act of occasioning an alteration in the existing state of things, the term *commodity* to the thing as altered; the term *product* including both commodities and services.

It is to be observed that, in ordinary language, a person is not said to produce a thing unless he has employed himself for that especial purpose. If an English oyster-fisher should meet with an oyster containing a pearl, he would be called not the producer of the pearl, but its casual finder. But a Ceylon oyster-fisher, whose trade is to fish for pearl oysters, is called a producer of pearls. The *mere existence* of the pearls is in both cases owing to the agency of nature; their existence as articles of value is in both cases owing to the agency of the fisher in removing them from a situation in which they were valueless. In the one case he did this intentionally, in the other accidentally. Attention is directed in the one case to *his* agency, and *he* is therefore called the producer of the pearl. In the other case it is directed to the agency of nature, and he is called only the appropriator. But it appears to us the more convenient classification, for scientific purposes, to term him in both cases the producer.

Economists have in general opposed consumption to production. They have defined consumption to be the destruction wholly, or in part, of any portion of wealth. And they consider it as the ultimate object of all production.

Tout ce qui est produit,* says M. Say, *est consommé; par conséquent, toute valeur créée est détruite, et n'a été créé que pour être détruite.*

"Consumption," says Mr. Malthus, "is the great purpose and end of all production."† "By consumption," says Mr. M'Culloch, "is meant the annihilation of those qualities which render commodities useful or desirable. To consume the products of Art and industry is to deprive the matter of which they consist of utility, and consequently of the exchangeable value communicated to it by labour. Consumption is, in fact, the end and object of human exertion, and when a commodity is in a fit state to be used, if its consumption be deferred, a loss is incurred."‡

That almost all that is produced is destroyed is true; but we cannot admit that it is produced for the purpose of being destroyed. It is produced for the purpose of being made use of. Its destruction is an incident to its use, not only not intended, but, as far as possible, avoided. In fact, there are some things which seem unsusceptible of destruction except by accidental injury. A statue in a gallery, or a medal, or a gem in a cabinet, may be preserved for centuries without apparent deterioration. There are others, such as food and fuel, which perish in the very act of using them, and hence, as these are the most essential commodities, the word consumption has been applied universally as expressing the making use of anything. But the bulk of commodities are destroyed by those numerous gradual agents which we call collectively *time*, and the action of which we strive to retard. If it be true that consumption is the object of all production, the inhabitant of a house must be termed its consumer, but it would be strange to call him its destroyer; since it would unquestionably be destroyed much sooner if uninhabited. It would be an improvement in the language of Political Economy if the expression "to use" could be substituted for that "to consume." There is, however, so much difficulty in changing an established nomenclature, that we shall continue to use the word consumption, premising that we use it to signify primarily the making use of a thing; a circumstance to which its destruction is generally, but not necessarily, incidental.

The wealth of a Country will much depend on the question, whether the tastes of its inhabitants lead them to prefer objects of slow or of rapid destruction.

It will depend, however, much more on their preference of productive or unproductive consumption.

Productive consumption is that use of a commodity which occasions an ulterior product. Unproductive consumption is, of course, that use which occasions no ulterior product. The characteristic of unproductive consumption is, that it adds to the enjoyment of no one but the consumer himself. Its only effect upon the rest of the community is to diminish *pro tanto* the mass of commodities applicable to their use.

Some commodities are unsusceptible of any but unproductive consumption; such are lace, embroidery, jewellery, and the other personal ornaments which are simply decorative, and afford neither warmth nor protection. Under this head may also be ranked tobacco and snuff, and the other stimulants, of which the best that can be said is, that they are not injurious. A much larger class of commodities is designed solely for productive use, and is never consumed unproductively, but by mistake. In this class are all tools, from the simplest to the most complicated; from the spade and the raft, to the steam engine and the Indiaman. But the generality of commodities may be used, according to the will of the proprietor, productively or unproductively; may be consumed so as to substitute some product in lieu of that which has been destroyed, or without any further beneficial result than the immediate pleasure which has accompanied their use. Whatever is capable of supporting human existence may be used to maintain those who are themselves producers, or those who are not. In the first case it is productively, in the second unproductively consumed.

The distinction between productive and unproductive *consumers* is less clearly marked than that between productive and unproductive *consumption*. To divide men into two classes, productive and unproductive consumers, would, in fact, be a false division, there being few who do not in some respects belong to both classes. So far as a man's consumption is essential to his production, he belongs to the first class; so far as it is not essential, to the second. Those only can be called simply unproductive who return nothing whatever for what they consume; those only simply productive who indulge in no superfluous consumption whatever.

To the first description belong those who, being provided, through their own previous exertions, or by the accidents of donation or inheritance, with a fund sufficient for their subsistence, are content to dedicate their revenue and their leisure to the purposes of mere enjoyment. This class is never large in any state of society. In an ignorant, and consequently a poor community, the number of those possessing a maintenance independent of exertion is necessarily small. Among civilized nations the love of accumulation, of power, of distinction, and of occupation, and the nobler desire of being more or less extensively useful, all powerfully counteract the slothful principles of our nature. As property becomes more secure, as the avenues to influence are opened, as merit and wealth rise in public estimation over the accidents of birth, as barbarous prejudices degrading to industry wear out, as the influence of sound religion teaches men that they were created for better purposes than selfish pleasure or useless mortification, in fact, as civilization improves, all the motives to voluntary exertion acquire force. And though the number of those who *might* live in idleness increases, the proportion of those who are unhappy enough to exercise that privilege diminishes.

Another class consists of those who derive their support solely from the spoil or the charity of others.

---

* Say, *Principles*, tome iii. p. 276.

† *Principles*, &c. p. 219.

‡ *Id.* p. 511—612. 2d Ed.

Production and consumption.

The number of those who live by rapine has obviously a tendency to diminish in the progress of civilization. About mendicancy there may be some doubt, as some superfluous wealth seems necessary to its existence, and it may be supposed likely to increase with the superfluity on which it feeds. That laws ill framed or ill administered may allow it so to increase we know, from our own experience. But there seems to be no reason to doubt that, under a wise system of commercial and municipal legislation, the number of able-bodied paupers might be so reduced as to be practically unimportant.

The last class of unproductive consumers consists of those whom age or infirmity has rendered permanently incapable of production. We say *permanently*, to exclude children, and those suffering under temporary disability. Though a child or an invalid make no immediate return, their support is the necessary condition of their future services. This is by far the largest of the unproductive classes, and one not likely to suffer relative diminution, the same causes which tend to obviate disease and injury tending also to prolong life where their effects are incurable. But from the information collected in the House of Commons' Report on Friendly Societies, 5th July, 1825, vol. iv., we are inclined to think that in this Country the class in question cannot amount to a fortieth part, or about two and a half per cent. of the whole community.

The number of absolutely productive consumers, that is, of persons who consume solely for the purpose of reproducing, is much smaller. It may be a question indeed whether in a Country free from slavery, or regulations resembling slavery, any such class is to be found. The humblest labourer has some expenses which are not essential to his health and strength. We endeavour to give to our domestic animals nothing beyond what is strictly necessary, and in the Countries where man is considered as a domestic animal it might be expected that the consumption of a slave would be equally limited. But even the slave generally acquires some peculium, which implies that his ordinary subsistence somewhat exceeds his wants.

It appears from this analysis that the bulk of the community are neither productive nor unproductive consumers, but may be referred to the one class or to the other, according to the portion of their expenses for the time being under consideration. So far as the husbandman takes just enough of the least expensive food, is just sufficiently clad with the simplest raiment, and inhabits a dwelling just sufficiently weather-tight and spacious to protect him from the seasons, he is a productive consumer. But his pipe and his gin, and generally speaking his beer, and the humble ornaments of his person and his dwelling, form his unproductive consumption.

We do not, of course, mean it to be inferred that all personal expenditure beyond mere necessaries is necessarily unproductive. The duties of those who fill the higher ranks in society can seldom be well performed unless they conciliate the respect of the vulgar by a certain display of opulence. If a Judge, or an Ambassador, required by his station to support an establishment costing £2000 a year, should spend £4000, half of his consumption would be productive, and the other half unproductive. It would be a great mistake, however, to consider the third footman behind his coach, though a mere useless weight to the horses, an unproductive consumer. What the footman consumes are his wages, and, so far at least as he consumes them in order to enable himself to perform his services as footman, he is a productive consumer. The things unproductively consumed are his services, and *they* are consumed by his master. Nor is it to be supposed, on the other hand, that all consumption even of necessaries by those who are themselves producers, is a productive consumption. The half-employed pauper whose labour is worth £10 a year, and whose consumption is £20, consumes unproductively the difference.

Instruments of production.

Having explained the nature of production and consumption, we now proceed to consider the agents by whose intervention production takes place.

I. Labour.

The primary instruments of production are labour, and those agents of which nature, unaided by man, affords us the assistance.

Labour is the voluntary exertion of bodily or mental faculties for the purpose of production. It may appear unnecessary to define a term having a meaning so precise and so generally understood. Peculiar notions respecting the causes of value have, however, led some Economists to employ the term labour in senses so different from its common acceptation, that for some time to come it will be dangerous to use the word without explanation. We have already observed that many recent writers have considered value as solely dependent on labour. When pressed to explain how wine in a cellar, or an oak in its progress from a sapling to a tree, could, on this principle, increase in value, they replied that they considered the improvement of the wine and the growth of the tree as so much additional labour bestowed on each. We do not quite understand the meaning of this reply; but we have given a definition of labour, lest we should be supposed to include in it the unassisted operations of nature. It may also be well to remind our readers that this definition excludes all those exertions which are not intended, immediately or through their products, to be made the subjects of exchange. A hired messenger, and a person walking for his amusement, a sportsman, and a gamekeeper, the ladies at an English ball, and a company of Natch girls in India, undergo the same fatigues; but ordinary language does not allow us to consider those as undergoing labour who exert themselves for the mere purpose of amusement.

II. Natural agents.

Under the term "the agents offered to us by nature," or, to use a shorter expression, "natural agents," we include every productive agent so far as it does not derive its powers from the act of man.

The term "natural agent" is far from being a convenient designation, but we have adopted it partly because it has been already made use of in this sense by eminent writers, and partly because we have not been able to find one less objectionable. The principal of these agents is the land, with its mines, its rivers, its natural forests with their wild inhabitants, and, in short, all its spontaneous productions. To these must be added the ocean, the atmosphere, light and heat, and even those physical laws, such as gravitation and electricity, by the knowledge of which we are able to vary the combinations of matter. All these productive agents have in general, by what appears to be an inconvenient synecdoche, been designated by the term *land;* partly because the land, as a source of profit, is the most important of those which are susceptible of appropriation, but chiefly because its possession generally carries with it the command over most of the others. And it is to be remembered that, though the powers of nature are necessary to afford a substratum for the other instruments of production to work upon, they are not of themselves, when universally accessible, causes of value. Limitation in supply is, as we have seen, a necessary constituent of value; and what is universally accessible is practically unlimited in supply.

III. Abstinence.

But although human labour, and the agency of nature, independently of that of man, are the primary productive powers, they require the concurrence of a third productive principle to give to them complete efficiency. The most laborious population, inhabiting the most fertile territory, if they devoted all their labour to the production of immediate results, and consumed its produce as it arose, would soon find their utmost exertions insufficient to produce even the mere necessaries of existence.

To the third principle, or instrument of production, without which the two others are inefficient, we shall give the name of *abstinence:* a term by which we express the conduct of a person who either abstains from the unproductive use of what he can command, or designedly prefers the production of remote to that of immediate results.

It was to the effects of this third instrument of production that we adverted when we laid down, as the third of our elementary propositions, that *the powers of labour and of the other instruments which produce wealth may be indefinitely increased by using their products as the means of further production.* All our subsequent remarks on abstinence are a developement and illustration of this proposition; we say developement and illustration, because it can scarcely be said to require formal proof.

The division of the instruments of production into three great branches has long been familiar to Economists. Those branches they have generally termed labour, land, and capital. In the principle of this division we agree; though we have substituted different expressions for the second and third branches. We have preferred the term natural agent to that of land, to avoid designating a whole genus by the name of one of its species: a practice which has occasioned the other cognate species to be generally slighted and often forgotten. We have substituted the term abstinence for that of capital on different grounds.

The term capital has been so variously defined that it may be doubtful whether it have any generally received meaning. We think, however, that, in popular acceptation, and in that of Economists themselves when they are not reminded of their definitions, that word signifies *an article of wealth, the result of human exertion, employed in the production or distribution of wealth.* We say the result of human exertion, in order to exclude those productive instruments to which we have given the name of natural agents, and which afford not profit, in the scientific sense of that word, but rent.

It is evident that capital, thus defined, is not a simple productive instrument; it is in most cases the result of all the three productive instruments combined. Some natural agent must have afforded the material, some delay of enjoyment must in general have reserved it from unproductive use, and some labour must in general have been employed to prepare and preserve it. *By the word abstinence, we wish to express that agent, distinct from labour and the agency of nature, the concurrence of which is necessary to the existence of capital, and which stands in the same relation to profit as labour does to wages.* We are aware that we employ the word abstinence in a more extensive sense than is warranted by common usage. Attention is usually drawn to abstinence only when it is not united with labour. It is recognised instantly in the conduct of a man who allows a tree or a domestic animal to attain its full growth; but it is less obvious when he plants the sapling or sows the seed corn. The observer's attention is occupied by the labour, and he omits to consider the additional sacrifice made when labour is undergone for a distant object. This additional sacrifice we comprehend under the term abstinence; not because abstinence is an unobjectionable expression for it, but because we have not been able to find one to which there are not still greater objections. We once thought of using "providence;" but providence implies no self-denial, and has no necessary connection with profit. To take out an umbrella is provident, but not in the usual sense of the word profitable. We afterwards proposed "frugality," but frugality implies some care and attention, that is to say, some labour; and though in practice abstinence is almost always accompanied by some degree of labour, it is obviously necessary to keep them separate in an analysis of the instruments of production.

It may be said that pure abstinence, being a mere negation, cannot produce positive effects; the same remark might as well be applied to intrepidity, or even to liberty, but who ever objected to their being considered as equivalent to active agents? To abstain from the enjoyment which is in our power, or to seek distant rather than immediate results, are among the most painful exertions of the human will. It is true that such exertions are made, and indeed are frequent in every state of society, except perhaps in the very lowest, and have been made in the very lowest, for society could not otherwise have improved; but of all the means by which man can be raised in the scale of being, abstinence, as it is perhaps the most effective, is the slowest in its increase, and the least generally diffused. Among nations those that are the least civilized, and among the different classes of the same nation those which are the worst educated, are always the most improvident, and consequently the least abstinent.

Capital.

We have already defined capital to be an article of wealth, the result of human exertion, employed in the production or distribution of wealth, and we have observed that each individual article of capital is in general the result of a combination of all the three great instruments of production—labour, abstinence, and the agency of nature.

When a man has possessed himself of any article of wealth, and resolves to employ it, not for the mere purposes of enjoyment, but as capital, or, in other words, as a means of further production, or of distribution, there appear to be eight modes in which his design may be effected.

1. He may intentionally destroy it, in order to obtain the effects which are the direct consequences of its destruction. The consumption of gunpowder in a mine, and of coals in the furnace of a steam-engine, afford instances. The food which every producer must consume in order to keep himself in the health and strength necessary to enable him to continue a producer is also thus consumed.

2. He may retain it and employ it for purposes of which its gradual destruction is the incidental but not the intended, or, in all cases, the necessary consequence. All implements and machinery are thus employed.

3. He may vary its form, as when materials are converted into finished commodities.

4. He may simply retain it until its value has been increased by changes occasioned by the lapse of time, or by an altered state of the market. The proprietor of a vineyard who, immediately after an abundant vintage, retains his wine, aims at both these advantages.

5. He may keep it ready for sale to meet the wants of his customers. A shopkeeper's finished articles or stock in trade are thus employed.

6. He may give it to the proprietor of some natural agent for the use of that agent; as when a farmer pays rent to his landlord.

7. He may give it to a labourer in exchange for his exertions; or, in other words, he may employ it in the payment of wages.

8. He may give it in exchange for some other commodity, to be itself employed as capital; or, in other words, he may use it commercially.

Most capitalists employ portions of their capital in all these eight modes.

If we suppose a wine retailer's capital to consist of the knowledge which he has acquired during his education for his business, of the warehouse and the simple machinery necessary to his trade, of the stock of commodities necessary for his own current consumption, and of one hundred pipes of wine in wood and in bottle, we shall find that *his knowledge, and machinery, and necessaries are destroyed without ever being directly exchanged*: the only difference being, first, that his knowledge remains unimpaired until either his death or his retirement from business makes it suddenly valueless, while his buildings, and machinery, and clothes, furniture, and food are consumed and replaced at successive periods; and, secondly, that the destruction of his food is immediate, and that of his buildings, machinery, furniture, and clothing is gradual. We shall find that of the wine he retains a portion until it shall have been improved by age, and keeps a portion as stock in trade ready for immediate sale, but ultimately sells the whole and pays away its price, partly in rent for the land covered by his buildings, partly in wages to his clerks, porters, shopmen, and other labourers, partly in keeping up his buildings and machinery, and partly in the repurchase of wine, bottles, and corks to keep up the stock in his warehouse and shop. What remains of the price of his wine, and something must remain, or he would be in a worse situation than one of his own labourers, is generally termed his *profit:* a part of it he must employ in replacing the stock of commodities necessary to keep himself in health and strength; the remainder he may employ either in his own personal enjoyment and that of his friends, which is an unproductive use, or in the increase of his own capital, or in creating a capital for some other person, in the education, for instance, of his son, which are productive uses.

Adam Smith has divided capital into fixed and circulating.

" There are two ways," he observes, " in which a capital may be employed so as to yield a revenue or profit.

" First, it may be employed in raising, manufacturing, or purchasing goods, and selling them again with a profit. The capital employed in this manner yields no revenue or profit to its employer while it either remains in his possession or continues in the same shape. The goods of the merchant yield him no revenue or profit till he sells them for money, and the money yields him as little till it is again exchanged for goods. His capital is continually going from him in one shape, and returning to him in another, and it is only by means of such circulation, or successive exchanges, that it can yield him any profit. Such capitals, therefore, may properly be called *circulating* capitals.

" Secondly, it may be employed in the improvement of land, in the purchase of useful machines and implements of trade, or in such like things as yield a revenue or profit without changing masters or circulating any further. Such capitals, therefore, may properly be called *fixed* capitals.

" The capital of a merchant is altogether a circulating capital. He has occasion for no machines or instruments of trade, unless his shop or warehouse be considered as such.

" Some part of the capital of every master artificer or manufacturer must be fixed in the instruments of his trade. This part, however, is very small in some, and very large in others. A master tailor requires no other instruments of trade than a parcel of needles; those of a master shoemaker are a little, though but a little, *more expensive.*

" In other works a much greater fixed capital is required. In a great iron work, for example, the furnace, the forge, the slit mill, are instruments of trade which *cannot be erected without a very great expense. That* part of the capital of the farmer which is employed in the instruments of agriculture is a fixed, that which is employed in the wages and maintenance of his labouring servants is a circulating, capital. He makes a profit of the one by keeping it in his own possession, and of the other by parting with it. A herd of cattle, bought in to make a profit by their milk and increase, is a fixed capital; the profit is made by keeping them. Their maintenance is a circulating capital; the profit is made by parting with it." Book ii. ch. i.

We are not aware that the principle of Adam Smith's division has ever been directly objected to. There may be some doubt, perhaps, whether the terms fixed and circulating are the best that could have been selected; but Adam Smith has stamped on them the meaning which he intended, and they have passed current in that signification ever since.

Mr. Ricardo, however, with the inattention to established usage which so much diminishes the usefulness of his writings, has used the terms fixed and circulating capital in a totally different sense. In this he has been followed by Mr. Mill; and as neither of these writers intimates that his use of the words is not the common one, it may be well to mark the difference.

" According as capital is rapidly perishable," says Mr. Ricardo, " and requires to be frequently reproduced, or is of slow consumption, it is classed under the heads of circulating or of fixed capital: a division not essential, and in which the line of demarcation cannot be accurately drawn. A brewer, whose buildings and machinery are valuable and durable, is said to employ a large portion of fixed capital; on the contrary, a shoemaker, whose capital is chiefly employed in the payment of wages, which are expended on food and clothing, commodities more perishable than buildings and machinery, is said to employ a large proportion of capital as circulating capital. Ch. i. sec. 4.

Mr. Ricardo might well remark that the line of demarcation between his two sorts of capital cannot be accurately drawn; for what can be more vague, or more void of positive meaning, than such comparative terms as slow and rapid? The singular circumstance is that both he and Mr. Mill should have supposed, and it appears clear that they did suppose, that their division followed that of Adam Smith. It is obviously a cross division. The master tailor's needles which Adam Smith selects as an example of fixed capital, because the tailor retains them, would, according to Mr. Ricardo, be circulating, because they are perishable. On the other hand, the materials and stock in trade of an iron founder would be circulating capital according to Smith, and fixed according to Ricardo.

We may be able to make the nature of capital, and Adam Smith's conception of it, still clearer by quoting his subdivision of fixed and circulating capitals.

"Fixed capital," he says, "consists chiefly of the four following articles:

"First, of all useful machines and instruments of trade which facilitate and abridge labour.

"Secondly, of all buildings used for the purpose of trade or manufacture; such as shops, warehouses, and farm-buildings, &c. They are a sort of instruments of trade, and may be considered in the same light.

"Thirdly, of the improvements of land, of what has been profitably laid out in clearing, draining, enclosing, manuring, and reducing it into the condition most proper for culture. An improved farm may be regarded in the same light as one of those useful machines which facilitate and abridge labour.

"Fourthly, of the acquired and useful abilities of all the members of the society. The acquisition of such talents by the maintenance of the acquirer during his education, study, or apprenticeship, costs an expense, which is a capital fixed and realized, as it were, in his person. The improved dexterity of a workman may be considered in the same light as a machine or instrument of trade which facilitates and abridges labour.

"The circulating capital is composed likewise of four parts:

"First, of the money by means of which all the other three are circulated and distributed to their proper consumers.

"Secondly, of the stock of provisions in the possession of the butcher, the grazier, &c., for the purpose of sale.

"Thirdly, of the materials, whether altogether rude or more or less manufactured, of clothes, furniture, and building, which are not yet made up, but remain in the hands of the growers, manufacturers, or merchants.

"Fourthly, of the work which is made up and completed, but is still in the hands of the merchant or manufacturer; such as the finished work in the shops of the smith, the goldsmith, the jeweller, and the china merchant. The circulating capital consists, in this manner, of the provisions, materials, and finished work of all kinds which are in the hands of their respective dealers, and of the money that is necessary for circulating and distributing them to their final consumers." Book ii. c. i.

This enumeration contains, perhaps, some useless distinctions, and, we think, two improper exclusions, but, generally speaking, it gives an excellent view of the different species of capital.

The things which appear to be improperly excluded are, first, the necessaries of life, consumed by the labourer and the capitalist for their own support; and, secondly, the houses and other commodities of slow consumption which the owner lets out to the consumer.

Adam Smith can scarcely be said to have explained his reason for excluding from the term capital the necessaries in the possession of the labourer. He merely observes that the labourer consumes as sparingly as he can, and derives his revenue only from his labour. The attention of Mr. Malthus has been drawn to the subject; he agrees in this respect with Adam Smith, and on the following grounds:

"The only productive consumption, properly so called, is the consumption or destruction of wealth by *capitalists* with a view to reproduction. This is the only marked line of distinction which can be drawn between productive and unproductive consumption. The workman whom the capitalist employs consumes that part of his wages which he does not save, as revenue, with a view to subsistence or enjoyment; and not as capital with a view to production." *Definitions*, p. 238.

Mr. Malthus would admit that the coals in the furnace of a steam-engine are productively employed; because their consumption is the necessary condition to the engine's performing its work. And in what does the consumption of food by a labourer differ from that of coals by a steam-engine? Simply in this, that the labourer derives pleasure from what he consumes, and the steam-engine does not. If a labourer were so constituted as to feel no craving for food, and no gratification from eating, and were reminded of its necessity only by the debility consequent on its want, would not his meals, taken as they would be solely to enable him to undergo his fatigues, be productively consumed? Nature has wisely enforced an act of daily necessity by the stimulus of hunger, and the reward of enjoyment, but do that stimulus and enjoyment detract from its productiveness? Is the ploughman's dinner less the means of his toils because he considers it as their end? Is not the food of working cattle productively employed? Does not the owner of a West Indian estate consider the supplies which he sends to his slaves as a capital destined to productive consumption?

Adam Smith has stated at length his reasons for excluding from the term capital the houses and other articles which the owner lets out to the consumer.

"One portion," he states, "of the stock of a society is reserved for immediate consumption, of which the characteristic is that it affords no revenue or profit. The whole stock of mere dwelling-houses makes a part of this portion. If a house be let to a tenant, as the house itself can produce nothing, the tenant must pay the rent out of some other revenue which he derives either from labour, or stock, or land. Where masquerades are common, it is a trade to let out dresses for the night. Upholsterers frequently let furniture by the month or the year. The revenue, however, which is derived from such things must always be ultimately derived from some other source of revenue. A stock of clothes may last for several years; a stock of furniture half a century or a century; but a stock of houses, well built and properly taken care of, may last many centuries. Though the period of their total consumption, however, is more distant, they are still as really a stock reserved for immediate consumption as either clothes or furniture." Book ii. ch. i.

This language would have been consistent if Adam Smith, like most of his successors, had confined the term capital to the instruments of further consumption. But we have seen that he includes under that term things incapable of productive consumption, if they have not reached the hands of those who are finally to use them. If a diamond necklace in a jeweller's shop be correctly termed capital, and Adam Smith has expressly stated that it is so, why is not a house which has been just finished by a speculative builder? It is difficult to perceive why he should have laid so much stress on the perishableness of the things in question. Perishableness and durability are not elements in the distinction between what is and what is not to be correctly termed capital. Many of the things which are used productively are of almost evanescent existence, such as the gas which lights a manufactory. On the other hand, the jewels of a noble family are not capital, though no limits can be assigned to their duration. It is at least conceivable that a house might be built so as not to require repair, and would this circumstance affect the question? In fact, however, the perishableness of these things is unfavourable to Adam Smith's view, as it shows their resemblance to things which he has admitted to be capital. A cellar of wine at a tavern-keeper's falls under his third class of circulating capitals; gradually the cellar is emptied, and when the last bottle has been drunk the capital is at an end. A house let ready furnished, a circulating library, a job carriage, a stage-coach, or a steam-packet, differs from the cellar of wine only because the progress of its consumption is less capable of being measured. Every day that it is used a portion wears away; and that portion is as much purchased and as much consumed by the hirer of the house or the carriage as the bottle of wine taken from the cellar. It is true that it may be consumed unproductively, and that in that case the hirer must pay the rent from some other revenue, as is the case with the price of *whatever* is unproductively consumed. But the portion of the house and furniture and carriage, for the time being unconsumed, is as much the capital, in the sense in which Adam Smith uses that word, of the upholsterer and the hackneyman, as the unconsumed portion of the wine is the capital of the tavern-keeper.

Capital may again be divided, according to the purposes to which it is applicable, into reproductive, simply productive, and unproductive.

We apply the term *reproductive* to all those articles of wealth which may be used to produce things of the same kind with themselves. All agricultural stock is reproductive; and so are all the necessaries of life. That portion of them which is consumed by the capitalists and labourers employed in producing necessaries is one of the means by which the regular supply is kept up. The coals in the furnace of a steam-engine used in working a coal mine, the iron instruments in an iron work, and a ship freighted with timber and naval stores are all reproductively employed.

We apply the term *simply productive* to those articles of wealth which, though instruments of production, cannot be employed in producing things of the same kind with themselves. A lace machine is simply productive. Its use is to make lace, but that lace cannot be employed to make a new machine. All the tools and machinery employed in the production of those things which cannot be productively consumed are themselves simply productive.

We apply the term *unproductive* or distributive capital to those commodities which are destined to unproductive use, but have not become the property of those who are to be their ultimate consumers.

A very great portion, perhaps the greater portion in value, of the commodities produced in an improved state of society, fall under this head at their first production.

We have already observed that, in every state of society, the number of absolutely unproductive *consumers* is small, and the number of absolutely productive consumers still smaller. But as wealth increases every man increases his unproductive *consumption*, until the whole amount in the whole society of such consumption may, and often does, exceed the whole amount of productive consumption. If we look through the shops of an opulent city we shall find the commodities destined to mere enjoyment far exceeding in value those destined to be employed in further production.

Some of Adam Smith's successors have excluded the things of which we are now speaking from the term capital. We have followed his example in including them, for two reasons.

First, because their exclusion is an unnecessary deviation from ordinary language. To say that a jeweller, with £50,000 worth of diamond ornaments in his shop, had no capital, would be an assertion of which few hearers would be able to guess the meaning.

But, in the second place, if it were possible to do, what certainly is much wanted, to form a new technical nomenclature for Political Economy, still we should include under the term capital the commodities in question. All Economists include under that term the materials and the instruments with which these commodities are formed. If the rough diamond and the gold in which it is to be set are capital while separate, it seems difficult to see what convenience there is in a nomenclature which denies them to be capital when united. Again, no Economist will doubt that a profit is received in proportion to the average time during which the commodities in question are retained by the capitalist. Why this profit is paid we shall endeavour to show hereafter, but the fact that it is paid may be assumed as unquestioned. But Economists are agreed that whatever gives a profit is properly termed capital.

The principal advantages derived from abstinence, or, to express the same idea in more familiar language, from the use of capital, are two: first the use of implements; and second the division of labour.

Implements, or tools, or machines (words which express things perhaps slightly different in some respects, but precisely similar so far as they are the subjects of Political Economy) have been divided into those which produce power, and those which transmit power. Under the first head are comprehended those which produce motion independently of human labour. Such are, for instance, those machines which are worked by the force of wind, of water, or of steam.

The second head comprises what are usually termed tools, such as the spade, the hammer, or the knife which assist the force, or save the time of the workman, but receive their impulse from his hand.

To these two classes a third must be added, including all those instruments which are not intended to produce or transmit motion, using that word in its popular sense. This class includes many things to which the name of implement, tool, or machine is not generally applied. A piece of land prepared for tillage, and the corn with which it is to be sown, are among the implements by whose use the harvest is produced. Books and manuscripts are implements more productive than those invented by Arkwright or Brunel. Again, many of the things which popularly *are* called implements, such as the telescope, have no reference to motion; and others, such as a chain, or an anchor, or indeed any fastening whatever, are intended not to produce or transmit, but to prevent it.

The instruments which derive their impulse from the person who works them are in general of a simple description, and some of them are to be met with in the rudest state of human society. The first subsistence offered by nature to the savage consists of the brutes around him; but some instruments beyond the weapons which she has given to him must enable him to take advantage of her bounty.

It will be observed that we consider the use of all implements as implying an exercise of abstinence, using that word in our extended sense as comprehending all preference of remote to immediate results. In civilized society this appears to be strictly true. It is obviously true as to the *use* of all those instruments and materials which may be used at will, either for the purpose of present enjoyment, or for that of further production, such, for example, as the greater part of agricultural stock. It is equally true as to the *making* of all those implements which are incapable of any but productive use, such as tools and machinery in the popular acceptation of those words. In an improved state of society, the commonest tool is the result of the labour of previous years, perhaps of previous centuries. A carpenter's tools are among the simplest that occur to us. But what a sacrifice of present enjoyment must have been undergone by the capitalist who first opened the mine of which the carpenter's nails and hammer are the product! How much labour directed to distant results must have been employed by those who formed the instruments with which that mine was worked! In fact, when we consider that all tools, except the rude instruments of savage life, are themselves the product of earlier tools, we may conclude that there is not a nail, among the many millions annually fabricated in England, which is not to a certain degree the product of some labour for the purpose of obtaining a distant result, or, in our nomenclature, of some abstinence undergone before the Conquest, or perhaps before the Heptarchy.

The same remark applies to the acquired abilities which Adam Smith has properly considered a capital fixed and realized in the person of their possessor. In many cases they are the result of long previous exertion and expense on his own part; exertion and expense which might have been directed to the obtaining objects of immediate enjoyment, but which have, in fact, been undergone solely in the hope of a distant reward. And in almost all cases they imply much expense, and consequently much sacrifice of immediate enjoyment on the part of parents or guardians. The maintenance of a boy during the first eight or nine years of his life is indeed an unavoidable burthen, and therefore cannot be considered a sacrifice. But almost all that is expended on him after that age is voluntary. At nine or ten he might earn a maintenance in an agricultural, and more than a bare maintenance in a manufacturing employment, and at twenty-one obtain better wages than at any subsequent period of his life. But even the lowest department of skilled labour is in general inaccessible except at an expense very great, when we consider by whom it is to be borne; £15 or £20 is a low apprentice fee, but amounts to half the average annual income of an agricultural family. The greater part of the remuneration for skilled labour is the reward for the abstinence implied by a considerable expenditure on the labourer's education.

We must admit, however, that this reasoning does not apply to society in that rude state which is not perhaps within the scope of Political Economy. The savage seldom employs in making his bow or his dart time which he could devote to the obtaining of any object of immediate enjoyment. He exercises therefore labour and providence, but not abstinence. The first step in improvement, the rise from the hunting and fishing to the pastoral state, implies an exercise of abstinence. Much more abstinence, or, in other words, a much greater use of capital, is required for the transition from the pastoral to the agricultural state; and an amount not only still greater, but constantly increasing, is necessary to the prosperity of manufactures and commerce. An agricultural Country can remain stationary; a commercial and manufacturing one cannot. The capital which fifty years ago enabled England to be the first of commercial and manufacturing nations was probably far inferior in extent and efficiency to that now possessed by France, or even to that of the late Kingdom of the Netherlands. If our capital had remained stationary, we should have sunk to a second or third rate power. The same consequence might now follow if commercial restraints, or the waste of a long war, should check the increase of our present capital, while that of our rivals should continue progressive.

Having shown the connection between abstinence and the employment of implements, the next thing to be considered is the advantage which the use of implements affords. This subject, however, we shall pass over very briefly; partly because an attempt to give any thing like an adequate account of it, however concise, would far exceed the limits of this Treatise; partly because the subject has been considered at some length in the Articles in this Encyclopædia on MECHANICS and MANUFACTURES; and partly because we believe all our readers to be aware that the powers of man are prodigiously increased by the use of implements, though probably no man ever had, or ever will have, sufficient knowledge of details and perception of their relations and consequences, to estimate the whole amount of that increase. A few remarks on those instruments which produce motion, or, as it is technically termed, *power*, are all that we can venture on.

The superior productiveness of modern compared with ancient labour depends, perhaps, principally on the use of these instruments. We doubt whether all the exertions of all the inhabitants of the Roman Empire, if exclusively directed to the manufacture of cotton goods, could, in a whole generation, have produced as great a quantity as is produced every year by a portion of the inhabitants of Lancashire; and we are sure that the produce would have been generally inferior in quality. The only moving powers employed by the Greeks or Romans were the lower animals, water, and wind. And even these powers they used very sparingly. They scarcely used wind except to assist their merchant vessels in a timid coasting; they used rivers as they found them, for the purposes of communication, but did not connect them by canals; they used horses only for burthen and draught, and the latter without the assistance of springs. They made little use of that powerful machine to which we give the general name of a mill, in which a single shaft, turning under the impulse of animal power, or wind, or water, or steam, enables a child to apply a force equal sometimes to that of a thousand workmen.

A ship of the line under full sail has been called the noblest exhibition of human power: it is, perhaps, the most beautiful. But if dominion over matter, if the power of directing inanimate substances, at the same time to exert the most tremendous energy, and to perform the most delicate operations, be the test, that dominion and power are no where so strikingly shown as in a large cotton manufactory. One of the most complete which we have seen is that constructed by the late Mr. Marsland at Stockport; and, as it exhibits very strikingly both the power and the manageableness of machinery, it may be worth while to give a short description of it, as we saw it in 1825.

Mr. Marsland was the proprietor of the Mersey for about a mile of its course, and of a tongue of land which two reaches of the river form into a peninsula. Through the isthmus of this peninsula he bored a tunnel sufficient to receive seven wheels of large diameter, and to give passage to enough of the river to turn them; these wheels communicated rotatory motion to perpendicular shafts; and the perpendicular shafts communicated the same motion to numerous horizontal shafts connected with them by pinions. Each horizontal shaft ran below the ceiling of a work-room more than a hundred-feet long. The buildings connected with the wheels worked by the river contained six or seven stories of work-rooms, each supplied with its horizontal shaft. The rotatory motion was carried on from each horizontal shaft by means of small solid wheels called drums, affixed to the principal shaft of each detached piece of machinery, and connected with the great horizontal shaft of the work-room by a leathern strap. Many of these rooms were not occupied by Mr. Marsland himself. He let out, by the hour, the day, or the week, a certain portion of the floor of a work-room, and the liberty to make use of a certain portion of the horizontal shaft. The tenant placed his own machinery on the floor, connected its drum with the shaft that revolved rapidly above, and instantly saw his own small mechanical world, with its system of wheels, rollers, and spindles, in full activity, performing its motions with a quickness, a regularity, and, above all, a perseverance, far beyond the exertions of man. In the operation of machinery, power, like matter, seems susceptible of indefinite aggregation and of indefinite subdivision. In the performance of some of its duties the machinery moved at a rate almost formidable, in others at one scarcely perceptible. It took hold of the cotton of which a neckcloth was to be made, cleaned it, arranged its fibres longitudinally, twisted them into a strong and continuous thread, and finally wove that thread into muslin. It took the wool of which a coat was to be made, and, after subjecting it to processes more numerous than those which cotton experiences, at last wove it into cloth. For thousands of years, in fact from the last great convulsion which traced the course of the river, until Mr. Marsland bored his tunnel, had the Mersey been wasting all the energy that now works so obediently.

One of the most striking qualities of machinery is its susceptibility of indefinite improvement. On looking through the instructive evidence collected by the Committee on Artisans and Machinery, (1824,) it will be found that nothing is more impressed on the minds of the witnesses than the constant tide of improvement, rendering obsolete in a very few years all that might have been supposed to be perfect.

Mr. Holdsworth, a spinner and machine-maker at Glasgow, states that the best mills at Glasgow are equal to the best mills at Manchester erected three or four years before. Mr. Holdsworth's history of his own proceedings will illustrate many of the previous observations.

He is asked whether he got his machinery from Manchester when he first commenced business. He replies: "I did not; I contemplated making it myself, and made the attempt, but there was so much difficulty in getting good workmen, and the expense of tools was so serious, that I desisted. I then selected a well-qualified young mechanic, and engaged him to make it for me. I gave over to him my patterns and my plans, and he executed well the machinery required in the first mill. Two years after I built a second mill, the machinery of which was also executed by him. After two years more I built a third and a larger mill, the machinery of which I made myself."

He is asked why he made the last machinery himself, and replies:

"In the first place that machine maker was very busy;" (it appears, subsequently, that, at the time of the examination, that maker could not have taken an order to execute any part of it under sixteen months, and that there were then eight or nine mills waiting for machinery, some of which had been ready for twelve months, and had only a small part of their machinery, and others had been ready six months and were empty:) "and as machine makers do not like to alter their plans, I could not prevail upon him to execute the improvements then recently made in Manchester." Fifth Report, p. 378.

Mr. J. Dunlop is asked (p. 473) how far he considers the American factories behind those of Glasgow. He replies, about thirty years. He goes on to state that they are in a progressive state, and the men very active and industrious. He is then asked whether, "supposing English machinery transported to America, with the assistance of English foremen, he does not think the population of America would soon be taught to work in their factories equally to the men of this Country!" He answers, "Yes, I think they would; but before they could acquire that we should be ahead of them a long way again. I reason comparing Scotland with England. We began the business of cotton-spinning later, we were of course behind, and we have always been behind; we have never been able to get up, and I believe never will."

Sixty years form a short period in the history of a nation; yet what changes in the state of England and the Southern parts of Scotland have the steam-engine and the cotton machinery effected within the last sixty years. They have almost doubled the population, more than doubled the wages of labour, and nearly trebled the rent of land. They enabled us to endure, not certainly without inconvenience, but yet to endure, a public debt more than trebled, and a taxation more than quadrupled. They changed us from exporters to importers of raw produce, and consequently changed our corn laws from a bounty on exportation to nearly a prohibition of importation. They have clad the whole world with a light and warm clothing, and made it so easy of acquisition that we are perhaps scarcely aware of the whole enjoyment that it affords.

There appears no reason, unless that reason be to be found among our own commercial institutions, why the improvements of the next sixty years should not equal those of the preceding. The cotton machinery is far from perfection; the evidence which we have quoted shows that it receives daily improvements; and the steam-engine is in its infancy: its first application to vessels is within our recollection; its application to carriages has scarcely commenced; and it is probable that many other powers of equal efficiency lie still undiscovered among the secrets of nature, or, if known, are still unapplied. There are doubtless at this instant innumerable productive instruments known but disregarded because separately they are inefficient, and the effect of their combination has not been perceived. Printing and paper are both of high antiquity. Printing was probably known to the Greeks; it certainly was practised by the Romans, as loaves of bread stamped with the baker's initials have been found in Pompeii. And paper has been used in China from times immemorial. But these instruments separately were of little value. While so expensive a commodity as parchment, or so brittle a one as the papyrus, were the best materials for books, the sale of a number of good copies sufficient to pay the expense of printing could not be relied on. Paper without printing was more useful than printing without paper; but the mere labour necessary to constant transcription, even supposing the materials to be of no value, would have been such as still to leave books an expensive luxury. But the combination of these two instruments, each separately of little utility, has always been considered the most important invention in the history of man.

The second of the two principal advantages derived from abstinence, or, in other words, from the use of capital, is the division of labour.

We have already observed that division of production would have been a more convenient expression than division of labour; but Adam Smith's authority has given such currency to the term division of labour, that we shall continue to employ it, using it, however, in the extended sense in which it appears to have been used by Adam Smith. We say *appears* to have been used, because Smith, with his habitual negligence of precision, has given no formal explanation of his meaning. But in the latter part of his celebrated first chapter, he appears to include among the advantages derived from the division of labour all those derived from internal and external commerce. It is clear, therefore, that, by division of labour, he meant division of production, or, in other words, the confining as much as possible each distinct producer and each distinct class of producers to operations of a single kind.

The advantages derived from the division of labour are attributed by Smith to three different circumstances. "First, to the increase of dexterity in every particular workman; secondly, to the saving of the time which is commonly lost in passing from one species of work to another; and lastly, to the invention of a great number of machines which facilitate and abridge labour, and enable one man to do the work of many."

Smith was the first writer who laid much stress on the division of labour. The force and the variety of the examples by which he has illustrated it make the first chapter perhaps the most amusing and the best known in his whole Work. But, like most of those who have discovered a new principle, he has in some respects overstated, and in others understated, its effects. His remark, "that the invention of all those machines by which labour is so much facilitated and abridged seems to have been originally owing to the division of labour," is too general. Many of our most useful implements have been invented by persons neither mechanics by profession, nor themselves employed in the operations which those implements facilitate. Arkwright was, as is well known, a barber; the inventor of the power-loom is a clergyman. Perhaps it would be a nearer approach to truth if we were to say that the division of labour has been occasioned by the use of implements. In a rude state of Society, every man possesses, and every man can manage, every sort of instrument. In an advanced state, when expensive machinery and an almost infinite variety of tools have superseded the few and simple implements of savage life, those only can profitably employ themselves in any branch of manufacture who can obtain the aid of the machinery, and have been trained to use the tools, by which its processes are facilitated; and the division of labour is the necessary consequence. But, in fact, the use of tools and the division of labour so act and react on one another, that their effects can seldom be separated in practice. Every great mechanical invention is followed by an increased division of labour, and every increased division of labour produces new inventions in mechanism.

> *Altera poscit opem res et conjurat amice.*

The increased dexterity of the workman, and the saving of the time which would be lost in passing from one sort of work to another, deserve the attention which they have received from Adam Smith. Both are consequences, and the first is a very important consequence of the division of labour. But he has passed by, or at least has not formally stated, other advantages derived from that principle which appear to be far more important.

One of the principal of these advantages arises from the circumstance that the same exertions which are necessary to produce a single given result are often sufficient to produce many hundred or many thousand similar results. The Post-office supplies a familiar illustration. The same exertions which are necessary to send a single letter from Falmouth to New York are sufficient to forward fifty, and nearly the same exertions will forward ten thousand. If every man were to effect the transmission of his own correspondence, the whole life of an eminent merchant might be passed in travelling, without his being able to deliver all the letters which the Post-office forwards for him in a single evening. The labour of a few individuals, devoted exclusively to the forwarding of letters, produces results which all the exertions of all the inhabitants of Europe could not effect, each person acting independently.

The utility of government depends on this principle. In the rudest state of society each man relies principally on himself for the protection both of his person and of his property. For these purposes he must be always armed, and always watchful; what little property he has must be movable, so as never to be far distant from its owner. Defence or escape occupy almost all his thoughts, and almost all his time, and, after all these sacrifices, they are very imperfectly effected. "If ever you see an old man here," said an inhabitant of the confines of Abyssinia to Bruce, "he is a stranger; the natives all die young by the lance."

But the labour which every individual, who relies on himself for protection, must himself undergo is more than sufficient to enable a few individuals to protect themselves, and also the whole of a numerous community. To this may be traced the origin of governments. The nucleus of every government must have been some person who offered protection in exchange for submission. On the governor and those with whom he is associated, or whom he appoints. is devolved the care of defending the community from violence and fraud. And so far as internal violence is concerned, and that is the evil most dreaded in civilized society, it is wonderful how small a number of persons can provide for the security of multitudes. About fifteen thousand soldiers, and not fifteen thousand policemen, watchmen, and officers of justice, protect the persons and property of the seventeen millions of inhabitants of Great Britain. There is scarcely a trade that does not engross the labour of a greater number of persons than are employed to perform this the most important of all services.

It is obvious, however, that the division of labour on which government is founded is subject to peculiar evils. Those who are to afford protection must necessarily be intrusted with power; and those who rely on others for protection lose, in a great measure, the means and the will to protect themselves. Under such circumstances, the bargain, if it can be called one, between the government and its subjects, is not conducted on the principles which regulate ordinary exchanges. The government generally endeavours to extort from its subjects, not merely a fair compensation for its services, but all that force or terror can wring from them without injuring their powers of further production. In fact, it does in general extort much more; for if we look through the world we shall find few governments whose oppression does not materially injure the prosperity of their people. When we read of African and Asiatic tyrannies, where millions seem themselves to consider their own happiness as dust in the balance compared with the caprices of their despot, we are inclined to suppose the evils of misgovernment to be the worst to which man can be exposed. But they are trifles compared to those which are felt in the absence of government. The mass of the inhabitants of Egypt, Persia, and Burmah, or to go as low as perhaps it is possible, the subjects of the Kings of Dahomi and Ashantee, enjoy security, if we compare their situation with that of the ungoverned inhabitants of New Zealand. So strongly is this felt that there is no tyranny which men will not eagerly embrace, if anarchy is to be the alternative. Almost all the differences between the different races of men, differences so great that we sometimes nearly forget that they all belong to the same species, may be traced to the degrees in which they enjoy the blessings of good government. If the worst government be better than anarchy, the advantages of the best must be incalculable. But the best governments of which the world has had experience, those of Great Britain and of the Countries which have derived their institutions from Great Britain, are far from having attained the perfection of which they appear to be susceptible. In these governments the subordinate duties are generally performed by persons specially educated for these purposes, the superior ones are not. It seems to be supposed that a knowledge of politics, the most extensive and the most difficult of all Sciences, is a natural appendage to persons holding a high rank in society, or may be acquired at intervals snatched from the bustle and the occupation of laborious and engrossing professions. In despotisms, the principal evils arise partly from the ignorance, and partly from the bad passions of the rulers. In representative governments, they arise principally from their unskilfulness. It is to be hoped that a further application of the division of labour, the principle upon which all government is founded, by providing an appropriate education for those who are to direct the affairs of the State, may protect us as effectually against suffering under ignorance or inexperience in our governors, as we are now protected against their injustice.

Another important consequence of the division of labour, and one which Adam Smith, though he has alluded to it, has not prominently stated, is the power possessed by every nation of availing itself, to a certain extent, of the natural and acquired advantages of every other portion of the commercial world. Colonel Torrens is the first writer who has expressly connected foreign trade with the division of labour, by designating international commerce as "the territorial division of labour."

Nature seems to have intended that mutual dependence should unite all the inhabitants of the earth into one commercial family. For this purpose she has indefinitely diversified her own products in every climate and in almost every extensive district. For this purpose, also, she seems to have varied so extensively the wants and the productive powers of the different races of men. The superiority of modern over ancient wealth depends in a great measure on the greater use we make of these varieties. We annually import into this Country about thirty million pounds of tea. The whole expense of purchasing and importing this quantity does not exceed £2,250,000, or about 1*s*. 6*d*. a pound, a sum equal to the value of the labour of only forty-five thousand men, supposing their annual wages to amount to £50 a year. With our agricultural skill, and our coal mines, and at the expense of above 40*s*. a pound instead of 1*s*. 6*d*., that is, at the cost of the labour of about one million two hundred thousand men instead of forty-five thousand, we might produce our own tea, and enjoy the pride of being independent of China. But one million two hundred thousand is about the number of all the men engaged in agricultural labour throughout England. A single trade, and that not an extensive one, supplies as much tea, and that probably of a better sort, as could be obtained, if it were possible to devote every farm and every garden to its domestic production.

The greater part of the advantage of rather importing than growing and manufacturing tea arises, without doubt, from the difference between the climates of China and England. But a great part also arises from the different price of labour in the two Countries. Not only the cultivation of the tea plant, but the preparation of its leaves, requires much time and attention. The money wages of labour are so low in China, that these processes add little to the money cost of the tea. In England the expense would be intolerable. When a nation, in which the powers of production, and consequently the wages of labour, are high, employs its own members in performing duties that could be as effectually performed by the less valuable labour of less civilized nations, it is guilty of the same folly as a farmer who should plough with a race-horse.

Another important consequence of the division of labour is the existence of retailers: A class who, without being themselves employed in the direct production of raw or manufactured commodities, are, in fact, the persons who supply them to their ultimate purchasers, and that at the times and in the portions which the convenience of those purchasers requires. When we look at a map of London and its suburbs, and consider that that province covered with houses contains more than a tenth of the inhabitants of England, and consumes perhaps one-fifth in value of all that is consumed in England, and obtains what it consumes, not from its own resources, but from the whole civilized world, it seems marvellous that the daily supply of such multitudes should be apportioned with any thing like accuracy to their daily wants. It is effected principally by means of the retailers. Each retailer, the centre of his own system of purchasers, knows, by experience, the average amount of their periodical wants. The wholesale dealer, who forms the link between the actual producer or importer, and the retailer, knows also, by experience, the average amount of the demands of his own purchasers, the retailers; and is governed by that experience in purchasing himself from the importer or producer. And the average amount of these last purchases affords the data on which the importers and producers regulate the whole vast and multifarious supply. It can scarcely be necessary to dwell on the further advantages derived from the readiness and subdivision of the retailer's stock; or, to point out the convenience of having to buy a steak from a butcher, instead of an ox from a grazier. These are the advantages to which we formerly referred, as enabling the retailer to obtain a profit proportioned to the average time during which his stock in trade remains in his possession.

We now proceed to show that the division of labour is mainly dependent on Abstinence, or, in other words, on the use of Capital.

"In that rude state of society," says Adam Smith, "in which there is no division of labour, in which exchanges are seldom made, and in which every man provides every thing for himself, it is not necessary that any stock should be accumulated or stored up beforehand in order to carry on the business of the society. Every man endeavours to supply, by his own industry, his own occasional wants as they occur. When he is hungry, he goes to the forest to hunt; when his coat is worn out, he clothes himself with the skin of the first large animal he kills; and when his hut begins to go to ruin, he repairs it as well as he can with the trees and the turf that are nearest to it.

"But when the division of labour has once been thoroughly introduced, the produce of a man's own labour can supply but a very small part of his occasional wants. The far greater part of them are supplied by the produce of other men's labour, which he purchases with the produce, or, what is the same thing, with the price of the produce of his own. But his purchase cannot be made until such time as the produce of his own labour has not only been completed, but sold. A stock of goods of different kinds, therefore, must be stored up somewhere, sufficient to maintain him, and to supply him with the materials and tools of his work, till such time, at least, as both these events can be brought about. A weaver cannot apply himself entirely to his peculiar business, unless there is beforehand stored up somewhere, either in his own possession, or in that of some other person, a stock sufficient to maintain him, and to supply him with the materials and tools of his work, till he has not only completed, but sold his web. This accumulation must evidently be previous to his applying his industry for so long a time to such a peculiar business." *Wealth of Nations*, book ii. *Introduction.*

Perhaps this is inaccurately expressed; there are numerous cases in which production and sale are contemporaneous. The most important divisions of labour are those which allot to a few members of the community the task of protecting and instructing the remainder. But their services are sold as they are performed. And the same remark applies to almost all those products to which we give the name of services. Nor is it absolutely necessary in any case, though, if Adam Smith's words were taken literally, such a necessity might be inferred, that, before a man dedicates himself to a peculiar branch of production, a stock of goods should be stored up to supply him with subsistence, materials, and tools, till his own product has been completed and sold. That he must be kept supplied with those articles is true; but they need not have been stored up before he first sets to work, they may have been produced while his work was in progress. Years must often elapse between the commencement and sale of a picture. But the painter's subsistence, tools, and materials for those years are not stored up before he sets to work: they are produced from time to time during the course of his labour. It is probable, however, that Adam Smith's real meaning was, not that the identical supplies which will be wanted in a course of progressive industry must be already collected when the process which they are to assist or remunerate is about to be begun, but that a fund or source must then exist from which they may be drawn as they are required. That fund must comprise in specie some of the things wanted. The painter must have his canvass, the weaver his loom, and materials, not enough, perhaps, to complete his web, but to commence it. As to those commodities, however, which the workman subsequently requires, it is enough if the fund on which he relies is a productive fund, keeping pace with his wants, and virtually set apart to answer them.

But if the employment of capital is required for the purpose of allowing a single workman to dedicate himself to one pursuit, it is still more obviously necessary in order to enable aggregations, or classes of producers, to concur, each by his separate exertions, in one production. In such cases even the mere matter of distribution, the mere apportionment of the price of the finished commodity among the different producers requires the employment of a considerable capital, and for a considerable time, or, in other words, a considerable exertion of abstinence. The produce of independent labour belongs by nature to its producer. But where there has been a considerable division of labour, the product has no *one* natural owner. If we were to attempt to reckon up the number of persons engaged in producing a single neckcloth, or a single piece of lace, we should find the number amount to many thousands; in fact, to many tens of thousands. It is obviously impossible that all these persons, even if they could ascertain their respective rights as producers, should act as owners of the neckcloth or the lace, and sell it for their common benefit.

This difficulty is got over by distinguishing those who assist in production by advancing capital, from those who contribute only labour—a distinction often marked by the terms master and workman; and by arranging into separate groups the different capitalists and workmen engaged in distinct processes, and letting each capitalist, as he passes on the commodity, receive from his immediate successor the price both of his own abstinence and of his workmen's labour.

It may be interesting to trace this process in the history of a coloured neckcloth or a piece of lace. The cotton of which it is formed may be supposed to have been grown by some Tenessee or Louisiana planter. For this purpose he must have employed labourers in preparing the soil and planting and attending to the shrub for more than a year before its pod ripened. When the pod became ripe, considerable labour, assisted by ingenious machinery, was necessary to extricate the seeds from the wool. The fleece thus cleaned was carried down the Mississippi to New Orleans, and there sold to a cotton factor. The price at which it was sold must have been sufficient, in the first place, to repay to the planter the wages which had been paid by him to all those employed in its production and carriage; and, secondly, to pay him a profit proportioned to the time which had elapsed between the payment of those wages and the sale of the cotton; or, in other words, to remunerate him for his abstinence in having so long deprived himself of the use of his money, or of the pleasure which he might have received from the labour of his work-people, if, instead of cultivating cotton, he had employed them in contributing to his own immediate enjoyment. The New Orleans factor, after keeping it perhaps five or six months, sold it to a Liverpool merchant. Scarcely any labour could have been expended on it at New Orleans, and, in the absence of accidental circumstances, its price was increased only by the profit of the cotton factor. A profit which was the remuneration of his abstinence in delaying, for five or six months, the gratification which he might have obtained by the expenditure on himself of the price paid by him to the planter. The Liverpool merchant brought it to England and sold it to a Manchester spinner. He must have sold it at a price which would repay, in the first place, the price at which it was bought from the factor at New Orleans; in the second place, the freight from thence to Liverpool; (which freight includes a portion of the wages of the seamen, and of the wages of those who built the vessel, of the profits of those who advanced those wages before the vessel was completed, of the wages and profits of those who imported the materials of which that vessel was built, and, in fact, of a chain of wages and profits extending to the earliest dawn of civilization;) and, thirdly, the merchant's profit for the time that these payments were made before his sale to the manufacturer was completed.

The spinner subjected it to the action of his work-people and machinery, until he reduced part of it into the thread applicable to weaving muslin, and part into the still finer thread that can be formed into lace.

The thread thus produced he sold to the weaver and to the lacemaker; at a price repaying, in addition to the price that was paid to the merchant, first, the wages of the work-people immediately engaged in the manufacture; secondly, the wages and profits of all those who supplied, by the labour of previous years, the buildings and machinery; and, thirdly, the profit of the master spinner. It would be tedious to trace the transmission of the thread from the weaver to the bleacher, from the bleacher to the printer, from the printer to the wholesale warehouseman, from him to the retailer, and thence to the ultimate purchaser; or even its shorter progress from the lacemaker to the embroiderer, and thence to the ultimate purchaser. At every step a fresh capitalist repays all the previous advances, subjects the article, if unfinished, to further processes, advances the wages of those engaged in its further manufacture and transport, and is ultimately repaid by the capitalist next in order all his own advances, and a profit proportioned to the time during which he has abstained from the unproductive enjoyment of the capital thus employed.

It will be observed, that we have not mentioned the taxation that must have been incurred throughout the whole process which we have described, or the rent that must have been paid for the use of the various appropriated natural agents whose services were requisite or beneficial. We have left rent unnoticed, because its amount depends so much on accident that any further allusion to it would have much increased the complexity of the subject. We have not expressly mentioned taxation, because it is included under the heads which we have enumerated. The money raised by taxation is employed in paying the wages and profits of those who perform, or cause to be performed, the most important of all services, the protecting the community from fraud and violence. Those who are thus employed afford precisely the same assistance to the merchant or the manufacturer, as the private watchman who protects the warehouse, or the smith who fortifies it with bars and padlocks.

Our limits prohibit our attempting to trace the gradual increase of the value of a pound of cotton from the time it was gathered on the banks of the Mississippi, till it appears in a Bond Street window as a piece of elaborate lace. We should probably be understating the difference if we were to say that the last price was a thousand times the first. The price of a pound of the finest cotton wool, as it is gathered, is less than two shillings. A pound of the finest cotton lace might easily be worth more than a hundred guineas. No means, except the separation of the functions of the capitalist from those of the labourer, and the constant advance of capital from one capitalist to another, could enable so many thousand producers to direct their efforts to one object, to continue them for so long a period, and to adjust the reward for their respective sacrifices.

Productiveness of Labour in Agriculture and Manufactures. Fourth Elementary Proposition.

Productiveness of labour in agriculture and manufactures.

Before we quit the subject of production, it is necessary to explain an important difference between the efficiency of the different productive instruments when employed in cultivating the earth, and their efficiency when employed in preparing for human use the raw produce obtained by agriculture: or, in other words, between the efficiency of agricultural and manufacturing industry. In the course of this discussion we shall illustrate the last of the four elementary propositions on which we believe the Science of Political Economy to rest; namely, Production. Productiveness of labour in agriculture and manufactures.

that, *agricultural skill remaining the same, additional labour employed on the land within a given district produces in general a less proportionate return.*

The difference between the efficiency of agricultural and of manufacturing industry which we have now to consider, consists in the power which agricultural industry possesses, and manufacturing industry does not possess, of obtaining an additional product from the same materials. We have seen that the use of implements and the division of labour assist the exertions of man to an extent quite incalculable at present, and apparently capable of indefinite increase. But manufacturing improvements, though they enable one man to do the work of hundreds or of thousands,—though they enable the same amount of labour employed on the same materials to produce a more and more useful commodity, cannot enable the same amount of labour, or even increased labour, employed on the same quantity of *materials*, to produce a much larger amount of finished work of the same quality, than could have been produced before. If the labour and the skill now employed throughout England on the manufacture of cotton were doubled, but the quantity of raw materials remained the same, the quantity of manufactured produce could not be sensibly increased. The value of that produce might perhaps be much increased, it might be made much finer, and consequently of greater length or breadth; but supposing the quality of the produce unaltered, its quantity could be increased only by the saving which might be made of that small portion of the raw material which now is wasted.

The case of agriculture is different. Those regions, indeed, which lie within the limits of perennial snow, or consist of rock or loose sand, or precipitous mountain, are unsusceptible of improvement. But with these exceptions, the produce of every extensive district seems capable of being almost indefinitely increased by constantly increasing the labour bestowed on it. Nothing appears more hopelessly barren than an extensive bog with its black-looking pools and rushy vegetation. But, by draining, by burning the limestone on which, in Ireland at least, it generally rests, and by employing the lime to convert the matted fibres of the turf into a vegetable mould, the bog may be made not only productive but fertile. There are about thirty-seven millions of acres in England and Wales. Of these it has been calculated that not eighty-five thousand, less in fact than one four-hundredth part, are in a state of high cultivation, as hop grounds, nursery grounds, and fruit and kitchen gardens; and that five millions are waste. All that is not waste is productively employed, but how small is its produce compared to the amount to which unlimited labour and abstinence might raise it! If the utmost use were made of lime and marl and the other mineral manures; if by a perfect system of drainage and irrigation water were nowhere allowed to be excessive or deficient; if all our wastes were protected by enclosures and planting, if all the land in tillage, instead of being scratched by the plough, were deeply and repeatedly trenched by manual labour; if minute care were employed in the selecting and planting of every seed or root, and watchfulness sufficient to prevent the appearance of a weed; if all live stock, instead of being pastured, had their food cut and brought to them; in short, if the whole Country were subjected to the labour which a rich citizen lavishes on his patch of suburban garden; if it were possible that all this should be effected, the agricultural produce of the Country might be raised to ten times, or indeed to much more than ten times its present amount. No additional labour or machinery can work up a pound of raw cotton into more than a pound of manufactured cotton; but the same bushel of seed-corn, and the same rood of land, according to the labour and skill with which they are treated, may produce four bushels, or eight bushels, or sixteen.

But although the land in England is capable of producing ten times, or more than ten times as much as it now produces, it is probable that its present produce will never be quadrupled, and almost certain that it will never be decupled.

On the other hand, unless our manufactures be checked by war, or by the continuance or introduction of legislative enactments unfavourable to their progress, their produce may increase during the next century at the same rate, or at a still greater rate, than it increased during the last century. It may be quadrupled, or much more than quadrupled.

The advantage possessed by land in repaying increased labour, though employed on the same materials, with a constantly increasing produce, is overbalanced by the diminishing proportion which the increase of the produce generally bears to the increase of the labour. And the disadvantage of manufactures in requiring for every increase of produce an equal increase of materials, is overbalanced by the constantly increasing facility with which the increased quantity of materials is worked up.

A century ago the average annual import of cotton wool into Great Britain was about one million two hundred thousand pounds. The amount now annually manufactured in Great Britain exceeds two hundred and forty millions of pounds. But though the materials now manufactured are increased at least two hundred times, it is obvious that the labour necessary to manufacture them has not increased two hundred times. It may be doubted whether it has increased thirty times. The whole number of families in Great Britain, exclusively of those employed in agriculture, amounted, at the enumeration in 1831, to 2.453,011; if we suppose the transport, manufacture, and sale of cotton to employ about one-eighth of them, or about 300,000 families, it is a large allowance. But with the inefficient machinery in use a century ago, the annual manufacture of one million two hundred thousand pounds of cotton could not have required the annual labour of less than ten thousand families. It probably required many more. The result has been that, although we now require two hundred times as much of the raw material as was required a century ago, and although that additional quantity of raw material is probably obtained from the soil by more than two hundred times the labour that was necessary to obtain the smaller quantity, yet, in consequence of the diminution of the labour necessary to manufacture a given amount, the price of the manufactured commodity (a price which exhibits the sum of the labour necessary for both obtaining the materials and working them up) has constantly diminished. In 1786, when our annual import was about twenty millions of pounds of cotton wool, the price of the yarn denominated No. 100 was 38*s*. a pound. In 1792, when the import amounted to thirty-four millions of pounds, the price of the same yarn was 16*s*. a pound. In 1806, when the import amounted to sixty millions, the price of the yarn had fallen to 7*s*. 2*d*. a pound; and with the increased quantity manufactured, it has now fallen below 3*s*. a pound. Every increase in the quantity manufactured has been accompanied by improvements in machinery, and an increased division of labour, and their effects have much more than balanced any increase which may have taken place in the proportionate labour necessary to produce the raw material.

The proposition that, in agriculture, additional labour generally produces a less proportionate result, or, in other words, that the labour of twenty men employed on the land within a given district, though it will certainly produce more than that of ten men, will seldom produce twice as much, will be best illustrated by confining our attention to a single example.

We will suppose a farm consisting of one thousand acres, two hundred very good land, three hundred merely tolerable, and the remainder barren down, affording only a scanty sheep-walk. We will suppose the farmer to employ upon it twenty men, and to obtain an average annual product, which, to reduce it to a single denomination, we will call six hundred quarters of wheat. We will suppose him now to double the number of his labourers, and we shall see what probability there is that the produce will consequently be doubled. If the twenty additional labourers are employed in cultivating the down land, they must necessarily produce a less return than that which is produced on the other land by the previous twenty, as the land is supposed to be worse. It is equally clear that their labour, if applied to the land already in cultivation, will be less productive than the labour previously applied to it; or, in other words, that the produce of that land, though increased, will not be doubled, since on no other principle can we account for any land except the very best having been ever cultivated. For if the farmer could have gone on applying additional labour to land already in cultivation without any diminution in the proportionate return, it is clear that he never would have cultivated the three hundred acres of inferior land. In fact, if this were the case, if additional labour employed in agriculture gave a proportionate return, he never need have cultivated more than a single acre, or even a single rood. It is probable that in the supposed case he would employ some of his additional labourers in breaking up a portion of the down, and some of them in cultivating more highly the land already in tillage. So employed, they might produce an additional crop of four hundred, or five hundred, or five hundred and fifty quarters, but it is certain that the additional crop would not be equal to the whole six hundred previously obtained: the produce would be increased, but would not be doubled.

This imaginary farm is a miniature of the whole Kingdom. We have in England large tracks of barren waste, and we have under cultivation soil of every description of fertility, from that which produces forty bushels of wheat an acre to that which produces, with the same labour, and on the same extent of land, only twelve or thirteen. If additional produce is to be raised, the resource, generally speaking, must be either the cultivation of what has been as yet untilled on account of its barrenness, or the employment of additional labour on what is now in cultivation. That in either case the additional produce is not likely to be in the proportion of the additional labour is as obvious in the case of the whole Kingdom as it has appeared to be in that of a single farm.

But the proposition which we have been endeavouring to illustrate, though general, is not universal; it is subject to material exceptions. In the first place, the negligence or ignorance of the occupier, or proprietor, or obstacles of ownership, often prevent for a long time particular portions of land from being subjected to the average degree of labour bestowed on land of equal capability. Increased labour, when at length bestowed on land so circumstanced, may fairly be expected to be as productive, indeed more productive, than the average of agricultural labour. Advantages of this kind have sometimes been derived from extensive operations of drainage and embankment; but the chances of great profit are so apt to blind men to the amount of physical obstacles, that projects of this kind are perhaps more frequently attempted prematurely than deferred till after the time when an increased demand for raw produce first rendered them fair speculations. Undertakings which have been postponed in consequence of obstacles arising from ownership are far more frequently productive. The enclosure of a common often subjects to the plough land of which the former unproductiveness was not owing to deficient fertility. Effects similar in kind, though not in degree, often take place when an estate becomes unfettered after the title has been long so circumstanced that the farmers could not rely on the duration or renewal of their leases. In these cases considerable additional produce may often be obtained by a comparatively small addition of labour.

But the most important exception to the general rule takes place when increase of labour is accompanied by increase of skill. More efficient implements, a better rotation of crops, a greater division of labour, in short, improvements in the art of agriculture, generally accompany the increase of agricultural labour. They always accompany that increase when it is accompanied by an increase of the capital as well as of the population of a Country; and they always counteract, and often outweigh, the inferiority or diminished proportional powers of the soil to which they are applied.

The total amount of the annual agricultural produce of Great Britain has much more than doubled during the last hundred years; but it is highly improbable that the amount of labour annually employed in agriculture has also doubled. It is not supposed that during that period the population of Great Britain has more than doubled; and the principal increase has till lately been in the manufacturing districts. The last hundred years, with all their misfortunes, form the most prosperous period of our History. We owe to them the enclosure of millions of acres formerly almost useless common field; we owe to them almost all that we possess that deserves the name of Agricultural Science; and we owe to them also all the canals, and almost all the roads, which, by obviating in a great measure the accidents of situation, enable the amount of labour to bear throughout the Kingdom something like an average proportion to the quality of the soil on which it is employed. It is possible, though certainly not probable, that our progress may be equal during the next hundred years; but though indefinite, it certainly cannot be infinite. It is obviously impossible that the produce of the soil of a given district can increase geometrically for ever, whatever be the amount of the labour employed on it.

On the other hand, every increase in the number of manufacturing labourers is accompanied not merely by a corresponding but by an increased productive power. If three hundred thousand families are now employed in Great Britain to manufacture and transport two hundred and forty millions of pounds of cotton, it is absolutely certain that six hundred thousand families could manu-

Production. Productiveness of labour in agriculture and manufactures.

facture and transport four hundred and eighty millions of pounds of cotton. It is, in fact, certain that they could do much more. It is not improbable that they could manufacture and transport seven hundred and twenty millions. The only check by which we can predict that the progress of our manufactures will in time be retarded, is the increasing difficulty of importing materials and food. If the importation of raw produce could keep pace with the power of working it up, there would be no limit to the increase of wealth and population.

Distribution.

Distribution.

Of the three great branches of Political Economy, the nature, the production, and the distribution of wealth, we have now considered the two former, and we proceed to treat of the last, namely, of the laws according to which all that is produced is *distributed* among those who become its ultimate consumers. In that state of society which is presupposed by the Political Economist, this is principally effected by means of exchange. We may indeed conceive a state of human existence admitting of this distribution without the intervention of exchanges. But such a situation of society, if it can be called society, neither deserves nor requires scientific investigation. Political Economy considers men in that more advanced state, which may fairly be called their natural state, since it is the state to which they are impelled by the provisions of nature, in which each individual relies on his fellows for the greater part, in many cases for the whole of what he consumes, and supplies his own wants principally or wholly by the exchanges in which he contributes to theirs.

But we must admit that we use each of the words production and exchange in a sense rather more extensive than is usual. We have already stated that we apply the word production to much that would commonly be called appropriation, and that we include under exchanges what are usually termed public burdens. We consider all that is received by the officers of Government as given in exchange for services affording protection, more or less complete, against foreign or domestic violence or fraud. It is true, as we have already remarked, that this exchange is conducted on peculiar principles. In those Governments which are not democratic or representative, the rulers themselves assess the amount which they are to receive, and generally assess it at the utmost which, under such circumstances, can be extorted from their subjects. And even under representative or democratic institutions, no individual inhabitant is permitted to refuse his share of the general contribution, though he should disclaim his share in the general protection. But the transaction, though often involuntary, and still more often inequitable, is still an exchange, and on the whole a beneficial exchange. The worst and most inefficient Government affords to its subjects a cheaper and a more effectual protection than they could obtain by their individual and unaided exertions.

The laws by which exchanges are regulated may be divided into two great branches. The one comprises those laws which apply generally to all exchanges; the other those which apply specifically to the respective kinds of exchanges in which the owners of the different productive instruments exchange specifically with one another the produce of those instruments.

In treating of the one we have to consider the general laws which regulate exchanges; in treating of the other, the relative proportions in which different classes of the community benefit by those laws. The things exchanged will be the principal subjects of the one discussion, the exchanging parties of the other.

Distribution. Nomenclature.

One of the greatest difficulties to which a writer on Political Economy is exposed, arises from the mutual dependence of the different propositions constituting the Science; a dependence which makes it difficult to explain any one without a frequent allusion to many others. And this is particularly the case with respect to distribution. The proportions in which different classes of the community are entitled to the things that are produced cannot be explained without a constant reference to the general laws of exchange; and, on the other hand, those laws cannot be discussed without a constant reference to the exchanging parties. Admitting, as we are forced to do, that no arrangement can be free from objection, we have thought that the least objectionable mode of presenting the subject of distribution will be to begin by a general classification of the parties among whom the results of the different instruments of production are divided; then to proceed to state the general laws of exchange; and, lastly, to point out the general circumstances which decide in what proportions the different classes of the community share in the general distribution.

According to the usual language of Political Economists, labour, capital, and land are the three instruments of production; labourers, capitalists, and landlords are the three classes of producers; and the whole produce is divided into wages, profit, and rent: the first designating the labourer's share, the second that of the capitalist, and the third that of the landlord. We approve, on the whole, of the principles on which this classification is founded, but we have been forced, much against our will, to make considerable alterations in the language in which it has been usually expressed; to add some new terms, and to enlarge and contract the signification of some others.

It appears to us that, to have a nomenclature which should fully and precisely indicate the facts of the case, not less than *twelve* distinct terms would be necessary. For each class there ought to be a name for the *instrument* employed or exercised, a name for the *class of persons* who employ or exercise it, a name for the *act* of employing or exercising it, and a name for the *share* of the produce by which that act is remunerated. Of these terms we have not much more than half, as will appear if we examine each class separately.

For the first class we have the terms "to labour," "a labourer," and "wages." Neither of these terms expresses the instruments of production: the substantive "labour," and the verb "to labour," express merely an act. "A labourer" is an agent, and wages are a result: but what is the thing employed? what is it that the labourer exerts? Clearly his mental or bodily faculties. With the addition of this term the nomenclature of the first class will be complete. To labour is to employ strength of body or mind for the purpose of production; the person who does so is a labourer, and wages are his remuneration.

In the second class we have the words capital, capitalist, and profit. These terms express the instrument, the person who employs or exercises it, and his remuneration; but there is no familiar term to express the act, the conduct of which profit is the reward, and which bears the same relation to profit which labour does to wages. To this conduct we have already given the name of abstinence. The addition of this term will complete the nomenclature of the second class. Capital is an article of wealth, the result of human exertion, employed in the production or distribution of wealth. Abstinence expresses both the act of abstaining from the unproductive use of capital, and also the similar conduct of the man who devotes his labour to the production of remote rather than of immediate results. The person who so acts is a capitalist, the reward of his conduct is profit.

The defectiveness of the established nomenclature is more striking when we come to the third class. Wages and profits are the creation of man. They are the recompense for the sacrifice made in the one case, of ease, in the other, of immediate enjoyment. But a considerable part of the produce of every Country is the recompense of no sacrifice whatever; is received by those who neither labour nor put by, but merely hold out their hands to accept the offerings of the rest of the community.

The powers of nature, as distinguished from those of man, are necessary to afford a field for the exercise of human abstinence and labour. Of these, some from their abundance and the notoriety of the means of employing them, are incapable of appropriation. Being universally accessible, they bear no price notwithstanding their utility; and what has been produced with their assistance has no value beyond that of the labour and abstinence which it has cost. It sells therefore for a price equal to, but not exceeding, the sum of the wages and profits which must be paid if the production is to be continued. The agency of nature is equally essential to the production of timber in the forests of Upper Canada and in England. But the supply of timber in the forests of Upper Canada is practically unlimited. No portion of the price of a Canadian hut is paid for the agency of nature in producing the logs of which it is constructed. The pine while standing was valueless. The purchaser pays only for the labour and abstinence necessary to fell and to fashion it.

But the assistance of an *appropriated* natural agent may render possible the production of a commodity more valuable than the result of equal labour and abstinence without such assistance. Such a commodity sells for a price exceeding the sum of the wages and profits which are sufficient to repay the capitalist and the labourer who have been employed on it. The surplus is taken by the proprietor of the natural agent, and is his reward, not for having laboured or abstained, but simply for not having withheld what he was able to withhold; for having permitted the gifts of nature to be accepted.

If we subtract from the price of an English oak what must be paid for the labour of him who planted the sapling, and for the abstinence of those who allowed it to grow for a century, still something is to be paid for the use of the land by which it was nourished. And that is the price of the agency not of man but of nature.

Of the agents afforded by nature, the principal is the land with its rivers, ports, and mines. In the rare cases in which the quantity of useful land is practically unlimited, a state of things which occurs only in the early stages of colonization, land is an agent universally accessible, and, as nothing is paid for its use, the whole produce belongs to the cultivators, and is divided, under the names of wages and profit, between the capitalists and the labourers, of whose abstinence and industry it is the result.

But in all old Countries, and even in colonies within a very few years after their foundation, certain lands, from peculiar advantages of soil or situation, are found to make more than the average return to a given expenditure of capital and industry. The proprietor of such lands, if he cultivate them himself, receives a surplus after having paid the wages of his labourers and deducted the profit to which he is entitled on his capital. He of course receives the same surplus if, instead of cultivating them himself, he lets them out to some other capitalist. The tenant receives the same profit, and the labourers receive the same wages as if they were employed on land possessing merely average natural advantages; the surplus forms the rent of the proprietor, or, as we usually term him, the landlord. The whole produce, instead of two, is divided into three shares—rent, profit, and wages. If the owner is also the capitalist or farmer, he receives two of these shares, both the profit and the rent. If he allow it to be cultivated by the capital of another, he receives only rent. But rent, with or without profit, he necessarily receives. And when the whole of a Country has been appropriated, though it be true, as will be shown hereafter, that some of the produce is raised by the application of additional capital without payment of additional rent, and may therefore be said to be raised rent free, yet it is equally true that a rent is received from every cultivated acre; a rent rising or falling according to the accidents of soil and situation, but the necessary result of limited extent and productive power.

It is obvious, however, as we have already stated, that land, though the principal, is not the only natural agent that can be appropriated. The mere knowledge of the operations of nature, as long as the use of that knowledge can be confined either by secrecy or by law, creates a revenue to its possessor analogous to the rent of land. The knowledge of the effect on the fibres of cotton of rollers moving with different velocities, enabled a village barber to found in a very few years a more than aristocratic fortune. Still greater wealth might probably have been acquired by Dr. Jenner, if he could have borne somewhat to limit the benefits which he has conferred on mankind.

When the author of a useful discovery puts it himself in practice, he is like a proprietor farming his own property; the produce, after paying average wages for the labour, and average profits for the capital, employed, affords a still further revenue, the effect not of that capital or of that labour, but of the discovery, the creation not of man but of nature. If, instead of using it himself, he let out to another the privilege of using it, he obtains a revenue so precisely resembling the rent of land that it often receives the same name. The payment made by a manufacturer to a patentee for the privilege of using the patent process is usually termed in commercial language a *rent*; and under the same head must be ranked all the peculiar advantages of situation or connection, and all extraordinary qualities of body and mind. The surplus revenue which they occasion beyond average wages and profits is a revenue for which no additional sacrifice has been made. The proprietor of these advantages differs from a landlord only in the circumstance that he cannot in general let them out to be used by another, and must consequently either allow them to be useless or turn them to account himself. He is forced, therefore, always to employ on them his own industry, and generally his own capital, and receives not only rent but wages and profit. If, therefore, the established division is adhered to, and all that is produced is to be divided into rent, profit, and wages,—and certainly that appears to be the most convenient classification;—and if wages and profit are to be considered as the rewards of peculiar sacrifices, the former the remuneration for labour, and the latter for abstinence from immediate enjoyment, it is clear that under the term "rent" must be included all that is obtained without any sacrifice; or, which is the same thing, beyond the remuneration for that sacrifice; all that nature or fortune bestows either without any exertion on the part of the recipient, or in addition to the average remuneration for the exercise of industry or the employment of capital.

But though we see no objection to this extension of the word rent, the terms land and landlord are too precise to admit of being equally extended. It would be too great an innovation to include under the term land every natural agent which is capable of appropriation, or under the term landlord every proprietor of such an agent. For these terms we must substitute those of *natural agent*, and *proprietor of a natural agent*. And the third class will then have a term for the third instrument of production, a term for the owner of that instrument, and a term for the share which he receives of the produce: terms corresponding with the terms faculties of body and mind, labourer, and wages, as applied to the first class, and with capital, capitalist, and profit, as applied to the second. We shall still want a term corresponding with labour and abstinence,—a term indicating the *conduct* which enables the proprietor of a natural agent to receive a rent. But as this conduct implies no sacrifice,—as it consists merely in not suffering the instrument of which he is the owner to be useless, it perhaps does not require a distinct designation. When a man possesses an estate, we take it for granted that he does not allow it to lie waste, but either uses it himself, or lets it to a tenant. In ordinary language the receipt of rent is included under the term ownership. There will therefore be little danger of obscurity if we consider the word "possess," when applied to the proprietor of a natural agent, as implying the receipt of the advantages afforded by that agent, or, in other words, of rent. Talents, indeed, often lie idle, but in that case they may be considered for economical purposes as not possessed. In fact, unaccompanied by the will to use them, they are useless.

But though the whole produce may be considered as divided into three shares, one of which is taken by the capitalists, another by the labourers, and another by the proprietors of the natural agents which have concurred in the production, it is very seldom that any given commodity, or the produce of any one productive exertion, is thus actually divided. The nearest approach to it takes place in those cases in which producers belonging to different classes become partners and agree that the produce of their joint exertions shall be sold and the price divided between them. Such a partnership is often formed between a capitalist and his labourers when the success of the enterprise depends much on the zeal of the labourers, and the capitalist is unable to overlook them. Such is the case in the Greenland fishery. The men seldom receive preascertained wages, but, on the termination of the voyage, the blubber is sold, and the price divided between the owners and the crew. The practice is the same in privateering, and probably in many other maritime speculations. Somewhat similar is the mode of letting land called the métayer system. Under that system, which is still common in the Continent of Europe, and probably is always to be found in a certain state of society, the landlord supplies the capital as well as the land, and receives half the crop, the remainder forming the wages of the tenant or head-labourer, and of the inferior work-people in his employ. But these are exceptions occasioned by the peculiarities of the adventure, or by the poverty or ignorance of imperfect civilization. The usual practice is to consider one of the parties as entitled to the whole product, paying to the others a price for their co-operation. The person so entitled is uniformly the capitalist: the sums which he pays for wages and rent are the purchase-money for the services of the labourer, and for the use of the natural agent employed.

In most cases a considerable interval elapses between the period at which the natural agent and the labourer are first employed, and the completion of the product. In this climate the harvest is seldom reaped until nearly a year after it has been sown; a still longer time is required for the maturity of oxen; and a longer still for that of a horse; and sixty or seventy years may pass between the commencement of a plantation, and the time at which the timber is saleable. It is obvious that neither the landlord nor the labourer, as such, can wait during all this interval for their remuneration. The doing so would, in fact, be an act of abstinence. It would be the employment of land and labour in order to obtain remote results. This sacrifice is made by the capitalist, and he is repaid for it by his appropriate remuneration, profit. He advances to the landlord and the labourer, and in most cases to some previous capitalist, the price of their respective assistance; or, in other words, the hire of the land and capital belonging to one, and of the mental and bodily powers of another, and becomes solely entitled to the whole of the product. The success of his operations depends on the proportion which the value of that produce, (or, in commercial language, the value of his returns) bears to the value of his advances, taking into consideration the time for which those advances have been made. If the value of the return is inferior to that of the advance, he is obviously a loser; he is a loser if it be merely equal, as he has incurred abstinence without profit, or, in ordinary language, has lost the interest on his capital. He is a loser even if the value of his returns do not exceed that of his advances by an amount equal to the current rate of profit for the period during which the advance has been made. In any of these cases the product is sold, so far as the capitalist is concerned, for less than the cost of its production. The employment of capital, therefore, is necessarily a speculation; it is the purchase of so much productive power which may or may not occasion a remunerative return.

The common language of Economists, therefore, which describes the landlord, the capitalist, and the labourer as sharers of the produce, is a fiction. Almost all that is produced is in the first instance the property of the capitalist; he has purchased it by having previously paid the rent and wages, and incurred or paid for the abstinence, which were necessary to its production. A portion of it, but generally a small portion, he consumes himself in the state in which he receives it; the re-

Distribution. Nomenclature.

mainder he sells. He may, if he think fit, employ the price of all that he sells in purchases for his own gratification; but he cannot remain a capitalist unless he consent to employ some portion of it in the hire of the land and labour, by the assistance of which the process of production is to be continued or recommenced. He cannot, generally speaking, fully retain his situation as a capitalist unless he employ enough to hire as much land and labour as before; and if he wish to raise himself in the world, he must, generally speaking, not merely keep up but increase the sum which he devotes to the purchase of productive force. If, for instance, he has hired the use of a farm for a year for £1000, and has paid £2000 more as wages to his labourers, and has expended £1000 in the purchase, from other capitalists, of agricultural stock, and at the end of the year has sold the produce for £4400, he may, if he like, spend on his own gratification the whole of that £4400; or he may so spend only £400, and employ the rest in hiring the farm and the labourers, and purchasing stock for another year; or he may spend on himself only £200, and by employing productively £4200 instead of £4000, hire more land, or more labourers, or purchase more stock and provide for the increase of his capital and his profit. But in whatever way he employ his £4400, he still must pay it to landlords, (using that word to comprise all proprietors of natural agents,) capitalists, and labourers.

It has been objected, however, that this nomenclature is incomplete. Rent, profit, and wages, it has been said, designate only those portions of the annual produce which the producers consume for their own gratification. They form the *revenue* of a nation. A further portion, and a very large one, must be employed not as revenue, but as capital; not in directly supplying the wants or directly ministering to the enjoyments of either landlords, labourers, or capitalists, but merely in keeping up the instruments of production. Thus of the farmer's whole return, which we have supposed to be of the value of £4400, we may suppose a portion, amounting in value to £200, to have consisted of corn which he returned to the earth as seed, and another portion, amounting to the same value, to have consisted of the forage which he gave to his working cattle. It has been said that neither this seed nor this forage was rent, profit, or wages.

The answer to this objection is, that the seed-corn and forage in question were the result of land, labour, and abstinence; they were entitled, therefore, when produced, to be denominated rent, wages, or profit, and the circumstance that they were employed to produce future instead of immediate gratification does not vary their character. When produced, they were revenue: their *conversion* into capital was a subsequent accident. No one would except against the expression that such and such a labourer has *saved part of his wages* and employed them in stocking his garden. If the words revenue and income were co-extensive with expenditure, the common statement, that a man is living within his income, would be a contradiction in terms.

Perhaps this may be made clearer if we retrace the history of capital.

The primary instruments of production were labour, and those productive agents which are spontaneously afforded by nature. The first dwellers on the earth had only rent and wages. The savage who, instead of devouring the animals which he had entrapped, reserved them to become the origin of a domesticated flock, and he who reserved, to be employed as seed, some of the grains which he had gathered, laid the foundation of capital. The produce of that flock and of that seed was partly rent, partly wages, and partly profit. And it did not cease to be so, although he refused to employ the whole of it on his immediate gratification.

It must be admitted, however, that the portion of the annual produce which is employed in the production or the support of brute or inanimate capital is not usually termed rent, wages, or profit. It has not, in fact, any specific name. But it appears to us to be the most philosophical arrangement to consider it as rent, wages, or profit, according to the character of its proprietor, without regard to its subsequent destination.

Exchange.

Having made this general classification of the parties among whom the results of the different productive instruments are divided, we now proceed to consider the general laws which regulate the proportions in which those results are exchanged for one another. To a certain degree this question was considered when we treated of value; but not having at that time explained the words production, wages, profit, or rent, we were unable to do more than to state and illustrate the following propositions:—

First, that all those things, and those things only, are susceptible of exchange, which, being transferable, are limited in supply, and are capable, directly or indirectly, of affording pleasure or preventing pain; a capacity to which we have affixed the name of utility. Secondly, that the reciprocal values of any two things, or, in other words, the quantity of the one which will exchange for a given quantity of the other, depend on two sets of causes; those which occasion the utility and limit the supply of the one, and those which limit the supply and occasion the utility of the other. The causes which occasion the utility and limit the supply of any given commodity or service, we denominated the *intrinsic* causes of its value. Those which limit the supply and occasion the utility of the commodities or services for which it is capable of being exchanged, we denominated the *extrinsic* causes of its value. And, thirdly, that comparative limitation of supply, or, to speak more familiarly, though less philosophically, comparative scarcity, though not sufficient to constitute value, is by far its most important element; utility, or, in other words, demand, being mainly dependent on it. We had not then shown the means by which supply is effected. Having done this, having shown that human Labour and Abstinence, and the spontaneous agency of Nature, are the three instruments of production, we are at liberty to explain what are the obstacles which limit the supply of all that is produced, and the mode in which those obstacles affect the reciprocal values of the different subjects of exchange.

In the following discussion, however, we shall in general substitute *price* or value in money for general value.

Price.

The general value of any commodity, that is, the quantity of all the other subjects of exchange which might be obtained in return for a given quantity of it, is incapable of being ascertained. Its specific value in any other commodity may be ascertained by the experiment of an exchange; the anxiety of each party in the exchange to give as little, and obtain as much as possible, leading him to investigate, as accurately as he can, the intrinsic causes giving value to each of the articles to be exchanged. This is, however, a troublesome operation, and many expedients are used to diminish its frequency. The most obvious one is to consider a single exchange, or the mean of a few exchanges, as a model for subsequent exchanges of a similar nature. By an extension of this expedient it may become a model for exchanges not of a similar nature. If given quantities of two different articles are each found by experience to exchange for a given quantity of a third article, the proportionate value of the two first-mentioned articles may, of course, be inferred. It is *measured* by the third. Hence arise the advantages of selecting, as one of the subjects of every exchange, a single commodity, or, more correctly, a species of commodities constituted of individuals of precisely similar qualities. In the first place, all persons can ascertain, with tolerable accuracy, the intrinsic causes which give value to the selected commodity, so that one half the trouble of an exchange is ready performed. And, secondly, if an exchange is to be effected between any other two commodities, the quantity of each that is usually exchanged for a given quantity of the third commodity is ascertained, and their relative value is inferred. The commodity thus selected as the general instrument of exchange, whatever be its substance, whether salt, as in Abyssinia, cowries, on the Coast of Guinea, or the precious metals, as in Europe, is *money*. When the use of such a commodity, or, in other words, of money, has become established, value in money, or *price*, is the only value familiarly contemplated. The scarcity and durability of gold and silver (the substances used as money by all civilized nations) make them peculiarly unsusceptible of alteration in value from intrinsic causes. On these accounts we think it better, in the following discussion, to refer rather to *price* than to general value, and to consider the value of money, so far as it depends on intrinsic causes, to be unvarying.

We must preface our explanation of the effect on price of the causes limiting supply, by a remark which may appear self-evident, but which must always be kept in recollection, namely, that *where the only natural agents employed are those which are universally accessible, and therefore are practically unlimited in supply, the utility of the produce, or, in other words, its power, directly or indirectly, of producing gratification, or preventing pain, must be in proportion to the sacrifices made to produce it, unless the producer has misapplied his exertions; since no man would willingly employ a given amount of labour or abstinence in producing one commodity, if he could obtain more gratification by devoting them to the production of another.*

We now revert to the causes which limit supply.

There are some commodities the results of agents no longer in existence, or acting at remote and uncertain periods, the supply of which cannot be increased, or cannot be reckoned upon. Antiques and relics belong to the first class, and all the very rare productions of Nature or Art, such as diamonds of extraordinary size, or pictures, or statues of extraordinary beauty, to the second. The values of such commodities are subject to no definite rules, and depend altogether on the wealth and taste of the community. In common language, they are said to bear a fancy price, that is, a price depending principally on the caprice or fashion of the day. The Boccaccio, which a few years ago sold for £2000, and after a year or two's interval for £700, may perhaps, fifty years hence, be purchased for a shilling. Relics which, in the IXth Century, were thought too valuable to admit of a definite price, would now be thought equally incapable of price in consequence of their utter worthlessness. In the following discussion we shall altogether omit such commodities, and confine our attention to those of which the supply is capable of increase, either regular, or sufficiently approaching to regularity, to admit of calculation.

The obstacle to the supply of those commodities which are produced by labour and abstinence, with that assistance only from nature which every one can command, consists solely in the difficulty of finding persons ready to submit to the labour and abstinence necessary to their production. In other words, their supply is limited by the cost of their production.

Cost of production.

The term "cost of production" must be familiar to those who are acquainted with the writings of modern Economists; but, like most terms in Political Economy, though currently used, it has never been accurately defined; and it appears to us impossible that it should have been defined without the assistance of the term "abstinence," or of some equivalent expression.

Mr. Ricardo, who originally introduced the term "cost of production," uses as an equivalent expression, "the quantity of labour which has been bestowed on the production of a commodity." Mr. Mill, ch. iii. sec. 2. appears to consider cost of production as equivalent to "quantity of labour." Mr. Malthus more elaborately defines it as "the advance of the quantity of accumulated and immediate labour necessary to production, with such a per centage upon the whole of the advances for the time they have been employed as is equivalent to ordinary profits." *Definitions*, p. 242.

In a note to the third edition, page 46, Mr. Ricardo admits that profit also forms a part of the cost of production. Mr. Mill, by a stretch of language, in the convenience of which we cannot concur, includes profit under the term labour. The definitions of Mr. Ricardo and Mr. Mill appear, therefore, to coincide. And that adopted by Mr. Malthus only differs from them in referring, not to the labour that *has* been employed, but to that which must be employed if the production must be continued. In this respect the language of Mr. Malthus is undoubtedly the most correct. The sacrifices that *have* been made to produce a given commodity have no effect on its value. All that the purchaser considers is the amount of sacrifice that its production would require at the time of the exchange. If the expense of producing a pair of stockings were suddenly to fall or to rise by one half, a rise or fall in the value of the existing stockings would be the consequence, although the labour that *has* been employed on them is of course unalterable. And when Mr. Ricardo and Mr. Mill speak of the labour which *has* been employed on a commodity as affecting its value, they must be understood as implying that the circumstances of production remain unchanged.

Colonel Torrens considers cost of production as equivalent to "the amount of capital expended on production," and refuses to consider profit as forming one of its elements. His remarks throw so much light on the whole subject, that we will venture to extract them at some length.

"Those writers who contend for the general equality of market and natural price, include the customary rate of profit under the term natural price, or cost of production. But this classification is highly unphilosophical and incorrect. The profits of stock never make any part of the expense of production; they are, on the contrary, a new creation brought into existence in consequence of this expense. The farmer, we will suppose, expends one hundred quarters of corn in cultivating his fields, and obtains in return one hundred and twenty quarters. In this case twenty quarters, being the excess of produce above expenditure, constitute the farmer's profit, but it would be absurd to call this excess or profit a part of the expenditure. The expenditure or cost of production was one hundred quarters. It has been now repaid with a surplus of twenty quarters; and, unless the surplus which remains after the expenditure is replaced be a part of the expenditure, unless, in fact, one hundred and twenty quarters be equal to a hundred, it is impossible that market price should be equivalent to natural. Supposing that corn is £3 per quarter, then, in the case we have stated, the natural price of the farmer's produce, or the one hundred quarters expended upon production, will be equivalent to £300; while the produce of one hundred and twenty quarters obtained in return will be equivalent to £360. The excess of market above natural price, or cost of production, is profit; and to contend that this profit is included in the cost of production, is the same thing as contending that the hundred quarters, or £300 laid out in cultivation, are equal to the one hundred and twenty quarters, or £360 thereby obtained.

"In manufacturing, as well as in agricultural industry, the profit of stock is distinct from the cost of production. The master manufacturer expends a certain quantity of raw material, of tools and implements of trade, and of subsistence for labourers, and obtains in return a given quantity of finished work. This finished work must possess a higher exchangeable value than the materials, tools, and subsistence, by the advance of which it was obtained; otherwise the master could have no inducement to continue his business. Manufacturing industry would cease, if the value produced did not exceed the value expended. But it is the excess of value which the finished work possesses above the value of the materials, implements, and subsistence expended, that constitutes the master's profit; and therefore we cannot assert that the profit of his stock is included in the cost of production without affirming the gross absurdity, that the excess of value above expenditure constitutes a part of expenditure. Supposing that the materials, tools, and subsistence cost £300, and that the finished work is worth £360, then the difference will be the master's profit; and we cannot maintain that the annual profit is included in the amount of expenditure, or cost of production, without urging the contradiction that £300 are equal to £360.

"The profit of stock, so far from forming any part of the cost of production, is a surplus remaining after this cost has been completely replaced. In carrying on their business, the farmer and manufacturer do not expend their profit, they create it. It forms no part of their first advances; on the contrary, it forms a part of their subsequent returns. It could not have been employed in carrying on the work of production, because, until this work was completed, it had no existence. It is essentially a surplus, a new creation, over and above all that is necessary to replace the cost of production, or, in other words, the capital advanced. It is hoped that enough has been said to convince the reader of the nature of the error into which those Economists fall who maintain that the profit of stock is included in the expense of production, and that natural and market price tend to an equality. Market price is that which we give in order to obtain a commodity by exchange in the market: natural price is that which we give to effect a purchase at the great storehouse of nature: it consists of the several articles of capital employed in production, and cannot by possibility include the surplus or profit created during the progress of production."*

Colonel Torrens's remarks are just, so far as they apply to the mere expressions which he is criticising. Profit is certainly not a means, but a result. It is true that unless that result were expected, production would not be continued. Neither the farmer nor the manufacturer could be induced by any other motive to abstain from the unproductive enjoyment of his capital; so food would not be produced unless its consumption were necessary or agreeable. But the obtaining a profit is no more a part of the cost of producing a harvest than the gratification of appetite is a part of the cost of producing a dinner, or protection from cold part of the cost of producing a coat.

Want of the term abstinence, or of some equivalent expression, has led Mr. Malthus into inaccuracy of language. He seems to have felt that something besides mere labour is essential to production. He felt that simple industry would not convert a naked heath into a valuable wood; that the planter, in addition to the labour of inserting and protecting the saplings, incurred the additional *sacrifice* of directing his labour to the production of remote results; and that the successive generations of proprietors, in suffering the young plantation to become mature, sacrificed their own emolument to that of their successors. He seems to have felt that these sacrifices were part of the cost of producing the wood, and, having no term to express them, he denominated them by the name of their reward. When he termed profit a part of the cost of production, he appears to us to have meant not profit, but that conduct which is repaid by profit: an inaccuracy precisely similar to that committed by those who term wages a part of the cost of production; meaning not wages, which are a result, but the labour for which wages are the remuneration.

Colonel Torrens's error is an error of omission. He refuses to consider profit as part of the cost of production, but he does not substitute for it abstinence or any equivalent expression. Although he admits that where equal capitals are employed the value of the products may differ if the one be brought to market sooner than the other, he has not stated the principle on which this difference depends. That principle is that, though in both cases the labour employed is the same, more abstinence is necessary in the one case than in the other.

By *cost of production*, then, we mean the sum of the labour and abstinence necessary to production. But cost of production, thus defined, must be divided into the cost of production on the part of the producer or seller, and the cost of production on the part of the consumer or purchaser. The first is of course the amount of the labour and abstinence which must be undergone by him who offers for sale a given class of commodities or services in order to enable him to continue to produce them. The second is, the amount of the labour and abstinence which must be undergone by those to whom a given commodity or service is offered for sale, if, instead of purchasing, they themselves, or some of them on the behalf of themselves and the others, were to produce it. The first is equal to the minimum, the second to the maximum of price. For, on the one hand, no man would continue to produce, for the purpose of sale, what should sell for less than it cost him to produce it. And, on the other hand, no men would continue to buy what they themselves, or some of them on the behalf of themselves and the others, could produce at less expense. With respect to those commodities, or, to speak more accurately, with respect to the value of those parts or attributes of commodities, which are the subjects of equal competition, which may be produced by all persons with equal advantages, the cost of production to the producer and the cost of production to the consumer are the same. Their price, therefore, represents the aggregate amount of the labour and abstinence necessary to continue their production. If their price should fall lower, the wages or the profits of those employed in their production must fall below the average remuneration of the labour and abstinence that must be undergone if their production is to be continued. In time, therefore, it is discontinued or diminished, until the value of the product has been raised by the diminution of the supply. If the price should rise beyond the cost of their production, the producers must receive more than an average remuneration for their sacrifices. As soon as this has been discovered, capital and industry flow towards the employment which, by this supposition, offers extraordinary advantages. Those who formerly were purchasers, or persons on their behalf, turn producers themselves, until the increased supply has equalized the price with the cost of production.

---

* Torrens, *On the Production of Wealth*, 51—55.

Some years ago London depended for water on the New River Company. As the quantity which they can supply is limited, the price rose with the extension of buildings, until it so far exceeded the cost of production as to induce some of the consumers to become producers. Three new Water Companies were established, and the price fell as the supply increased, until the shares in the New River Company fell to nearly one-fourth of their former value; from £15,000 to £4000. If the metropolis should continue to increase these transactions will recur. The price of water will increase and exceed the cost at which it could be afforded. New Companies will arise, and, unless the additional supply is checked by greater natural obstacles than those which the existing Companies have to surmount, the price will again fall to its present level.

But though, under free competition, cost of production is the regulator of price, its influence is subject to much occasional interruption. Its operation can be supposed to be perfect only if we suppose that there are no disturbing causes, that capital and labour can be at once transferred, and without loss, from one employment to another, and that every producer has full information of the profit to be derived from every mode of production. But it is obvious that these suppositions have no resemblance to the truth. A large portion of the capital essential to production consists of buildings, machinery, and other implements, the results of much time and labour, and of little service for any except their existing purposes. A still larger portion consists of knowledge and of intellectual and bodily dexterity, applicable only to the processes in which those qualities were originally acquired. Again, the advantage derived from any given business depends so much upon the dexterity and the good fortune with which it is managed, that few capitalists can estimate, except upon an average of some years, the amount of their own profits, and still fewer can estimate those of their neighbours. Established businesses, therefore, may survive the causes in which they originated, and become gradually extinguished as their comparative unprofitableness is discovered, and the labourers and capital engaged in them wear away without being replaced; and, on the other hand, other employments are inadequately supplied with the capital and industry which they could profitably absorb. During the interval, the products of the one sell for more, and those of the others for less, than their cost of production. Political Economy does not deal with particular facts but with general tendencies, and when we assign to cost of production the power of regulating price in cases of equal competition, we mean to describe it not as a point to which price is attached, but as a centre of oscillation which it is always endeavouring to approach.

We have seen that, under circumstances of equal competition, or, in other words, where all persons can become producers, and that with equal advantages, the cost of production on the part of the producer or seller, and the cost of production on the part of the consumer or purchaser, are the same, and that the commodity thus produced sells for its cost of production; or, in other words, at a price equal to the sum of the labour and abstinence which its production requires; or, to use a more familiar expression, at a price equal to the amount of the wages and profits which must be paid to induce the producers to continue their exertions. It has lately been a general opinion that the bulk of commodities is produced under circumstances of equal competition. "By far the greater part of those goods," says Mr. Ricardo, (*Principles*, &c. p. 3.) "which are the objects of desire are produced by labour, and may be multiplied almost without any assignable limit if we are disposed to bestow the labour necessary to obtain them. In speaking then of commodities, of their exchangeable value, and of the laws which regulate their relative prices, we always mean such commodities only as can be increased in quantity by the exertion of human industry, and in the production of which competition operates without restraint."

Now it is clear that the production in which no appropriated natural agent has concurred, is the only production which has been made under circumstances of perfectly equal competition. And how few are the commodities of which the production has in no stage been assisted by peculiar advantages of soil, or situation, or by extraordinary talent of body or mind, or by processes generally unknown, or protected by law from imitation. Where the assistance of these agents, to which we have given the general name of natural agents, has been obtained, the result is more valuable than the result of equal labour and abstinence unassisted by similar aids. A commodity thus produced is called the subject of a *monopoly*; and the person who has appropriated such a natural agent, a *monopolist*.

Monopolies.

Monopolies may be divided into four kinds.

1. Where the monopolist has not the exclusive power of producing, but only certain exclusive facilities as a producer, and can increase, with undiminished, or even increased facility, the amount of his produce.

The value of a commodity produced under such cir-

Distribution. Price. Monopoly.

cumstances approaches more nearly to the cost of production on the part of the seller, than that of any other monopolized commodity. It is obvious that its price can never permanently fall below the value of the sacrifices which must be made by the producer, and, on the other hand, that it never can permanently rise above the value of the sacrifices which must be made by the consumers, if, instead of purchasing, they, or some persons in their behalf, were to turn producers. Sir R. Arkwright's yarn could not sell for more than yarn of an equal quality produced without the aid of his patent machinery; nor would Arkwright have sold it for less than the value of the labour and abstinence employed in its production. The first was the cost of production to the consumer, the second the cost of production to the producer. But the difference between the two was enormous; the cost to Arkwright was not one-fifth of what it would have been to his customers.

His inventions enabled him to produce a greater quantity, but not a better quality. The finger and thumb constitute an instrument more delicate than any system of rollers, and the muslin formed by the comparatively unassisted labour of the Hindoo is finer and more durable than the produce of our elaborate manufactories. The price which Arkwright *could* exact was therefore limited, as we have seen, by the competition of other productive instruments, more expensive but quite as efficient. The price which he *did* exact was still further limited by a regard to his own interest. He had discovered an instrument of which the powers, instead of being exhausted, increased with every increase in its application. To erect a mill for the purpose of spinning annually a hundred or a thousand pounds of cotton would be madness. The expense of spinning ten thousand pounds very little exceeds the expense of spinning one thousand, and forty thousand might probably be spun at less than double the expense of ten thousand. As the quantity produced is increased, the relative cost of production is diminished. If, therefore, on the sale of ten thousand pounds weight of yarn at a given price, which we will call £10,000, his profit amounted to £5000, the profit of selling one hundred thousand weight at the same price might have amounted to £90,000, and his profit on selling one million pounds weight to £900,000. But to effect this was obviously impossible. As value depends mainly on limitation of supply, he could not have at once offered a large quantity for sale without diminishing the price, if he left that price to be fixed by the competition of the purchasers, or without having a large portion unsold, if he refused to submit to that diminution. His only mode of stimulating a constant increase of consumption was to submit to such a constant lowering of price as should constantly widen the circle of those able and willing to purchase. As is usually the case, his own interest and that of the public coincided, and led him to accept a price far exceeding indeed the cost of production to himself, but falling short by a still wider interval of what would have been the cost of production to them.

Sir R. Arkwright's monopoly, therefore, was of the most limited kind. His remuneration was bounded, and it was not his interest even to approach that boundary.

2. A second kind of monopoly is in the opposite extreme. It exists where price is checked neither by the hopes nor by the fears of the producer, where no competition is dreaded, and no increased supply can be effected. The owners of some vineyards have such a monopoly. Constantia owes its peculiar flavour to the agency of a few acres of ground, and that flavour would be destroyed if high cultivation were employed to force from that ground a larger quantity of wine. As no person but the proprietor of the Constantia farm can be a producer, the price is not checked by any cost of production to the consumer. It is not checked by any wish of the proprietor to increase the consumption, since the quantity produced, and consequently the quantity consumed, is incapable of increase. The price cannot of course fall below the cost of production, but may indefinitely exceed it. It is limited solely by the will and the ability of the consumers. And if fashion were to make it an object of intense desire among the opulent, a pipe of Constantia, produced perhaps at the expense of £20, might sell for £20,000.

3 A third and more frequent kind of monopoly lies between these two extremes, and is neither so strict as the last, nor so comparatively open as the first. This comprises those cases in which the monopolist is the only producer, but, by the application of additional labour and abstinence, can indefinitely increase his production. The book trade affords an illustration. While a work is protected by copyright, no person but the proprietor of that copyright can produce copies: and he may multiply them indefinitely by the application of additional labour and abstinence. There is here no cost of production on the part of the purchaser, and, as far as he is concerned, the price is limited only by his will and ability. The efficient check arises from the interest of the publisher. As is the case with manufactures generally, the relative expense of publication diminishes as the number of copies published increases. It is his interest, therefore, to encourage a large sale by affixing a price but slightly exceeding the cost of production, diminished as that cost is by the magnitude of the produce. A hundred copies of *Waverly* might perhaps, have been sold at ten guineas a copy; but there can be no doubt that a larger aggregate profit was obtained by selling ten thousand at a guinea and a half.

4. The fourth and last class of monopolies exists where production must be assisted by natural agents, limited in number, and varying in power, and repaying with less and less relative assistance every increase in the amount of the labour and abstinence bestowed on them. It is under these circumstances that the greater part of the raw produce, whatever it be, which is the staple food of the inhabitants in every Country, potatoes in Ireland, wheat in England, or rice in India, is produced. It is, in fact, the great monopoly of land; and as there are scarcely any commodities of which the supply is not in some measure limited by the limited extent of the land essential or serviceable to some process in their production, all general theories as to value must be subject to error until the general laws regulating the value of the assistance to be derived from land have been ascertained. It will be necessary, therefore, to examine them at some length.

Land.

The soil of every extensive district is of different degrees of fertility and convenience of situation, and the soils of each degree constitute a distinct class of natural agents, affording each a distinct amount of assistance to the cultivator. And we have seen that each portion of soil, whatever be its fertility, agricultural skill remaining the same, generally gives a less and less proportionate return to each additional quantity of labour and abstinence bestowed on its cultivation, and may be said, therefore, to comprise within itself a system of natural agents of different powers. The different classes of natural agents will be successively employed, in proportion to their efficiency; an inferior class being never resorted to while a superior one is equally accessible: and each class, until it has been completely appropriated, may be considered as practically unlimited in supply, since it is universally accessible. What shall be the worst natural agent employed, or, in other words, to what extent inferior soils shall be cultivated, or additional labour and abstinence employed at a comparative disadvantage on the cultivation of those which are more fertile or better situated, must always be determined by the wealth and wants of the community; by the quantity of agricultural produce which they have the power and the desire to purchase. While those wants can be satisfied by slightly cultivating only a portion of the most fertile and best situated land, that land, though highly productive, indeed more productive in proportion to the labour and abstinence bestowed on it than at any subsequent stage, cannot be a separate and independent source of value. It is then a natural agent universally accessible and its produce, however large, will exchange only for the value of the labour and abstinence employed on its production. In short, the cost of production to the producer, and the cost of production to the consumer, are, under such circumstances, the same. This is the state of some of the fertile and thinly peopled districts of the tropics. The inhabitants of the greater part of the Tierra Caliente of Mexico appropriate at will from the fertile wilderness over which they are scattered the small patches which afford them the materials of lodging, food, and raiment. We are told that in these districts the labour of a week will provide subsistence for a year, but even this vast productive power, or even any conceivable increase in it, is incapable of giving value to the assistance afforded as long as the supply of that assistance remains unlimited.

It becomes limited, however, in the very earliest stages of improvement. Both the causes and the consequences of this event may be illustrated by tracing the progress of a colony.

When a body of emigrants arrives on the coast of an unoccupied district, their first operation must be to fix the situation of their future metropolis; the seat of government, of law, of foreign trade, and of those manufactures which require the congregation of numerous workmen. We may suppose their numbers and the local advantages to be such as to enable them to occupy, within such a distance from their infant town as to render the expense of carriage immaterial, as much land of the highest fertility as each agricultural family may wish to cultivate. The agricultural produce thus obtained must sell for its cost of production to the producer; every consumer being able at will to turn a producer, with advantages equal to those enjoyed by the existing producers, and being unwilling to give for the result of a given amount of labour and abstinence on their part more than the result of an equal amount of labour and abstinence on his own part. Such a community rapidly increases in numbers and in wealth, and that increase is accompanied by an increased desire and ability to purchase agricultural produce. Until the supply of raw produce has been increased, the price must now rise above the cost of production. But when the most fertile lands within a given distance of the town have been occupied, there remain only three modes of increasing the supply: either 1. by cultivating the fertile lands at a greater distance from the town; or, 2. by cultivating the inferior land in its neighbourhood; or, 3. by employing additional labour and abstinence in the cultivation of the lands already occupied. Whichever of these plans be adopted, and probably they will all be adopted, the additional quantity must be supplied at an increased expense. The first is loaded with the expenses of carriage; and we know that a given amount of labour and abstinence is employed to comparative disadvantage, when applied either to the cultivation of inferior land, or to the further improvement of the best land.

The immediate consequence of the increase of supply must be a fall of price, but a fall not equal to the previous rise. The additional supply is produced under circumstances of equal competition, every consumer having it in his power to turn producer by occupying the more distant or less fertile territory; it sells, therefore, for the cost of production to the producer. But commodities of precisely the same qualities cannot sell in the same market for different prices. The purchaser of a bushel of wheat does not inquire whether it was grown within a furlong or at ten miles from the place of sale. The produce, therefore, of the fertile lands in the immediate vicinity of the market sells at the same price as that of the distant or inferior land.

That price, as it is equal to the cost of production of what is produced at the greatest expense, must exceed the cost of production of what is produced at the least expense. The proprietor of the most fertile and best situated land has no motive to take less, as he cannot, like the owner of a patent, increase the amount of what he produces and continue to produce at equal advantage; and the purchaser cannot support an offer of less, as he cannot turn producer but by submitting to disadvantages which equalize the current price and the cost of production.

As the colony grows into a people and an empire the same processes are repeated. Every increase of wealth and population raises the price of raw produce. Increase of price occasions an increase of supply, raised at a comparatively greater expense. The price falls in consequence of the increased supply, but is prevented from falling to its former level by the increase which has taken place in the cost of producing that part of the whole supply which is brought to market at the greatest expense.

The effect will be the same whether we select for the scene a continent or an island; a district containing soils of every degree of fertility, or of precisely uniform quality. The Anglo-Americans have supplied their constantly increasing wants chiefly by spreading themselves backwards over their unbounded Western territory, and have made little use of inferior soils, or of high cultivation, except in the immediate vicinity of their cities. In Malta, a single acre receives more labour than would be devoted to a square mile in the Illinois; but precisely the same motives impel the Maltese to terrace his mountains into gardens, and the American to reclaim the prairies of the Missouri.

It may be inferred, from the picture which we have given of the progress of society, that we believe an increased difficulty of obtaining raw produce to be the natural incident to an increase of population. In the absence of counteracting causes it certainly would be so; but those causes are so powerful, that, unless checked by legislation, they in many respects balance the causes which we have been considering. In a colony, the counteracting causes appear likely to preponderate for a period, the duration of which must of course depend in part on the quantity of fertile and unoccupied land in its vicinity. As the circle of appropriated land expands, and the expense of bringing food to the consumers becomes more oppressive, there is a tendency in the consumers to follow the food. The colonial capital, now turned into a metropolis, may continue to send out portion after portion of her increased inhabitants until the whole territory acquires something approaching to an average amount of cultivation. Again, in every Country increased wealth and numbers are accompanied by increased agricultural skill and improved means of transport. The use of implements, the division of labour, and physical knowledge are powerful aids to the agriculturist, though they do not afford to him the almost magical increase of power which they give to the manufacturer. The improvements in carriage are still more important: a given amount of labour applied for twenty years to a given piece of land would probably now produce a return four or five times as great as would have been obtained at the Conquest. But the labour necessary to transport that produce one hundred miles is probably now not one one-hundredth of what it was then. No improvements in husbandry instruments, or in breeding, or in the rotation of crops, have been so efficient as the substitution of the waggon, the Macadamized road, the canal, the navigable river, and the railway, for the pack-horse of our ancestors and the dangerous tracks through which they beat out and picked their way. The intervention of a hill or a morass was then an obstacle sufficient to allow the price of corn on one side to be double that on the other; and London was so dependent on the immediately adjacent Counties that the landlords of those Counties petitioned against the opening of roads, as interfering with their vested right to a monopoly of the metropolitan supply; a petition which failed because the immediate interest of other landlords opposed it.

But the principal means by which a Country, when increasing in wealth and population, may avoid the necessity of raising its raw produce at a constantly increasing disadvantage is by importation.

We have seen that additional labour employed in manufactures produces an increasing proportionate effect; that if one thousand men can in a given time work up one million of pounds of cotton, two thousand men would be able to work up in the same time more than two millions of pounds, and four thousand men, much more than twice as much as two thousand. As a nation increases in opulence and population, it becomes the interest, therefore, of the community to devote their additional population rather to manufactures, in which they have a constantly increasing advantage, than to agriculture, at a constantly increasing disadvantage. As their industry becomes more and more efficient, they are in general able to purchase with the produce of a given amount of labour and abstinence larger and a larger amount of the produce of the industry of their less advanced contemporaries. The produce of the labour of a single Englishman employed for a given time in fabricating cotton will purchase the cotton grown by the labour of five, or perhaps ten, Hindoos, or the wheat grown by three, or perhaps five, Lithuanians or Poles.

It must be recollected, indeed, that a nation while extending its manufactures must increase its importation of raw produce; and we have already stated that the increased labour at which the additional produce must be obtained would retard the progress of such a community. But though this is unquestionable, though it is even certain that, if sufficient time be allowed, this obstacle is able, not merely to retard, but almost to arrest, the advance of manufactures, there seems to be little to fear from it within any of those periods within which calculations for practical purposes are generally confined. In the first place, the stimulus of an advantageous trade must tend to increase the agricultural skill of the exporting nations, and increase the facilities of transport; causes which, especially in the earlier stages of a nation's improvement, often enable it, and for considerable periods, to bring to market an increased quantity of raw produce with the same or even less proportionate labour. And, secondly, even if we suppose the manufacturing nation to be supplied by its agricultural customers at an increased proportionate expense to *them*, it does not follow that the proportionate expense to *her* need be increased. The increased difficulty on the one side may be balanced by the increased facility on the other. We will suppose that at present one hundred thousand yards of muslin, fabricated by twelve Englishmen, can be exchanged for one hundred and fifty quarters of wheat, raised by thirty-six Poles; that an increase in population of one-third makes it necessary to import two hundred instead of one hundred and fifty quarters, and that the two hundred quarters are raised, not by forty-eight, the former proportion, but by sixty Poles. If the increase in our skill has kept pace with our increase of numbers, it is probable that eighteen Englishmen, instead of one hundred and fifty thousand, the former proportion, would be able to fabricate at least two hundred thousand yards of muslin. The exchange under such circumstances, instead of being less, would be more beneficial than before. England would purchase more corn, and Poland more muslin, at a less proportionate amount of labour.

It must be carefully remembered that the preceding remarks apply not to the higher or lower *price* of raw produce, but to the greater or less difficulty in obtaining it; things which have no necessary connection; one of them depending on the causes which affect the general value of raw produce, the other on the causes which affect the general value of money. At the same time, and in the same place, the prices of articles exactly measure the difficulty of obtaining them. It is exactly half as difficult to get a commodity that costs one sovereign as to get a commodity that costs two. But this is only true at the same time and in the same place. Though in England a quarter of corn now costs about fifty shillings, and in the reign of Henry VIII. cost about twenty, it is probable that it was then more difficult to obtain one than it is now. This must have been the case if it was then more difficult to obtain twenty shillings than it is now to obtain fifty. It is equally clear that, although a quarter of wheat now costs in England about ten ounces of silver, and about six ounces in Poland, yet, if it is easier in England to obtain ten ounces of silver than in Poland to obtain six ounces, it is easier in England to obtain a quarter of wheat than it is in Poland. Experience shows that wealth and population almost always increase together, though not in equal ratios, the increase of wealth being, as we have already stated, generally greater than the increase of population. The increased capital and labour of an increasing population are naturally directed to manufactures, in which, as we have already seen, every increased production is more easily effected. As their labour becomes more productive, the value of the products of a given quantity of that labour rises in the general market of the world; or, in other words, they obtain in return for it a greater amount of the precious metals; or, in other words, a higher price. Therefore, although they may have to pay a higher price for a given quantity of raw produce, whether of home growth or imported, it does not follow that the difficulty of obtaining that given quantity has increased; it is possible, and not improbable, that it may have diminished. A nation so situated may be compared to an individual whose income happens to be rising at the same time when the price of corn is rising. If the rise of his income more than counterbalances the rise of corn, he finds it every year more easy to purchase a given quantity, though he may have to give a higher and higher price for it.

We have seen that production may take place under five different circumstances.

1. Absence of monopoly; all persons being capable of producing with equal advantage.

2. A monopoly under which the monopolist has not the exclusive power of producing, but exclusive facilities as a producer, which may be employed indefinitely with equal or increasing advantage.

3. A monopoly under which the monopolist is the only producer, and cannot increase the amount of his produce.

4. A monopoly under which the monopolist is the only producer, and can increase indefinitely, with equal or increasing advantage, the amount of his produce.

5. A monopoly under which the monopolist is not the only producer, but has peculiar facilities which diminish and ultimately disappear as he increases the amount of his produce.

The price of those commodities which are comprehended in the first class appears to be subject to laws capable of accurate investigation. Where labour alone has been employed, the price must be equal to the wages of that labour. Where that labour has been assisted by abstinence, or, in other words, where a period has elapsed between the employment of the labour and the sale of its produce, the price must be equal to the amount of the wages of that labour and the remuneration to be paid either to the labourer for having suffered the payment of his wages to be deferred, or to the capitalist who has paid those wages in advance.

There are, however, very few commodities of which the whole price can be resolved into the remuneration for the labour, or the abstinence, or both, which must be bestowed on their production.

Mere abstinence can produce nothing. Labour, or the agency of nature, must afford the subject with respect to which it is to be exercised. It is possible, indeed, that a natural agent universally accessible may sometimes afford a product of no value at first, but capable of becoming valuable by mere keeping; but no instance of the kind occurs to us, and some little trouble is generally requisite for the mere safe custody of any article.

Mere labour *does* produce a very few articles. The laver collected and sold on the coast of Devonshire is an example. It grows naturally on the unappropriated rocks within the influence of the tide, and in abundance practically unlimited. No instruments are necessary to gather or prepare it, and, as it will not keep, it is sold as soon as it has been collected and washed. The price of a given quantity consists, therefore, merely of the wages of those who gather, wash, and bring it to market.

A class of commodities, perhaps rather larger, but still inconsiderable when compared with the general mass, is produced by labour and abstinence, assisted only by those natural agents which are universally accessible. It is difficult, however, to point out an article, however simple, that can be exposed to sale without the concurrence, direct or indirect, of many hundred, or, more frequently, of many thousand different producers; almost every one of whom will be found to have been aided by some monopolized agent.

There are few things of which the price seems to consist more exclusively of wages and profits than a watch;* but if we trace it from the mine to the pocket of the purchaser, we shall be struck by the payment of rent (the invariable sign of the agency of some instrument not universally accessible) at every stage of its progress. Rent was paid for the privilege of extracting from the mines the metals of which it is composed; for the land which afforded the materials of the ships in which those metals were transported to an English port; for the wharfs at which they were landed, and the warehouses where they were exposed to sale; the watchmaker pays a rent for the land covered by his manufactories, and the retailer for that on which his shop is situated. The miner, the shipwright, the house-builder, and the watchmaker all use implements formed of materials produced by the same processes as the materials of the watch, and subject also in their different stages to similar payments of rent. The whole amount of all these different payments forms probably a very small portion of the value of the watch, but if we were to attempt to enumerate them they would be found subdivided into ramifications too minute for calculation. What remains consists of the wages of the workmen, and the profits of the capitalists who paid those wages in advance. The attempt to trace back these wages and profits to their earliest beginnings would be as vain as the attempt to enumerate all the payments of rent. In estimating, therefore, the value of a manufactured commodity, we seldom go further back than to the price paid by the manufacturer for his materials and implements, a price which must have included all previous payments of rent, wages, and profits.

We will now trace the causes which increase the value of those materials after they have been the property of the manufacturer. We will suppose a watchmaker's capital to consist of materials worth £500, that he has bought the land covered by his buildings for £500, and has expended £900 in erecting them, that his tools have cost him £100, and that an annual expense of £100 is necessary to keep his buildings and tools in repair. We will suppose him to employ ten workmen, each receiving at an average £100 a year, and that one year is the average period from the commencement to the sale of a watch. We will suppose that his ten workmen can annually convert his £500 worth of materials into five hundred watches, and that the average rate of profit in his business amounts to ten per centum per annum. To give him this profit it is clear that his watches must sell for

---

* It has been used by M. Canard, M. Flores Estrada, and Mr. M'Culloch, as an example of the value derived from labour alone.

Value of materials	£500
Wages for a year	1000
Repairs for a year	100
	1600
Profit on the advance of these sums and on the value of the land, and buildings, and tools, for half a year, at ten per cent. per annum	155
	£1755

It will be observed that, although a year is supposed to elapse between the commencement and the sale of a watch, we suppose the cost of its production to have been advanced for only half a year. The fact is that some part of the advances must have been made for more, and some for less than half a year. Supposing a workman to have been employed on the watch for a year, and paid daily, he received his first day's wages one year before the watch was sold, but his last day's wages on the very day of the sale; six months, therefore, is the average period for which the whole were advanced before the sale; just as large a proportion having been advanced for a shorter as for a longer period.

It will be observed, too, that we suppose the whole value of the materials, repairs, and wages to be repaid, but only a profit on the value of the land, buildings, and tools. The first are annually expended by the capitalist, the second remain to be used as instruments of further production. The land is indestructible, and the damage done to the buildings and tools is paid for by the £100 supposed to be expended in repairs.

But the whole cost of production has not yet been enumerated.

In the first place, some wages must be allowed to the master watchmaker himself for his labour in superintending his business; and, secondly, some profit on the expense of his education. And as his knowledge and habits, which form his mental capital, will not survive him, something more than the average rate of profit is necessary to replace their value.

If we suppose the expense of his education to have amounted to £1000, and that it will be replaced with average profit by an annual return of £15 per cent., and the average wages of labour to be £30 a year, we have £180 to add to the price of the watches, and £9 more for the advance of this sum for half a year, making £1944.

The last source of expense is taxation, or, in other words, the wages and profits of those who have protected all the different producers of the watches from foreign and domestic violence and fraud. A considerable portion of the price paid by the watchmaker for his materials, tools, and buildings, probably consisted of the taxation to which those commodities had been previously subjected; but the taxation which we are now considering is that which he incurs during the year supposed to be employed in manufacturing the watch.

This is an expense little capable of previous estimation; partly because the expenses of government are subject to constant variation, and partly because no general principle regulates the proportions in which those expenses are divided among the contributors. In England they are in general imposed upon the persons using or producing certain commodities; upon the use, for instance, of a carriage or window, and upon the production of candles or glass. We will suppose the annual taxation imposed on the shop and other instruments of production used by the watchmaker to amount to £53 7*s*., the profit on the advance of this sum for half a year would exceed by a slight fraction £2 13*s*., together £56, making with the £1944, the amount of our previous calculation, the sum of £2000, the whole cost of production of the five hundred watches, or £4 a piece.

The different sums in this example have of course been taken at random; but we have thought it worth while to go through it partly as an instance of the calculations on which every manufacturer must found his estimate of the profit or loss likely to follow any given undertaking; and partly to show in how many shapes, labour, abstinence, and the agency of nature, or, in other words, rent, profits, and wages, are constantly reappearing in every productive process.

When we speak, therefore, of a class of commodities as produced under circumstances of equal competition, or as the result of labour and abstinence unassisted by any other appropriated agent, and consider their price as equal to the sum of the wages and profits that must be paid for their production, we do not mean to state that any such commodities exist, but that, if they did exist, such would be the laws by which their price would be regulated; and that so far as labour or abstinence, or both, are conducive to the production of any given commodity, it is to be considered as produced under circumstances of equal competition, and as worth the wages or profits, or both, with which that labour or abstinence, or both, must be remunerated.

The prices of the commodities comprised in the second, third, and fourth classes are but little governed by any general rules. The prices of those comprised in the second class cannot rise above the cost of production when unassisted by the monopolized agent, but have a tendency to approach the cost of production to the monopolist. The prices of those comprised in the third and fourth classes have no necessary limits, but approach much more nearly to the cost of production in the fourth class, where the monopolist can increase his produce, than in the third class, where nature strictly limits the amount that can be produced.

The price of the commodities comprised in the fifth and last class, those which are produced under what may be called unequal competition or qualified monopoly, where all persons may become producers, but every additional quantity is obtained at a greater proportionate expense, has a constant tendency to coincide with the cost of production of that portion which is continued to be produced at the greatest expense. The annual supply of London requires about one million five hundred thousand quarters of wheat. Of this quantity, perhaps fifty thousand can be obtained only by means of high cultivation, or very distant carriage, at an expense of about 50*s*. a quarter. While the wants and the wealth of the inhabitants of London are such as to make them require, and enable them to purchase, one million five hundred thousand quarters, and the expenses of carriage and cultivation remain unaltered, it is clear that the whole quantity, supposing it to be of uniform quality, must sell at the rate of 50*s*. a quarter. If it were to sell for less, the last fifty thousand quarters would cease to be produced, and the price would again rise in consequence of the deficiency of the supply. But of the whole one million five hundred thousand quarters, a portion, perhaps fifty thousand, might be produced by slightly cultivating the most fertile and best situated land, at the expense of 10*s.* a quarter. A hundred thousand may cost the producer 20*s.* a quarter, two hundred thousand 25*s.*, two hundred thousand more 30*s.* a quarter, and the cost of production of all, except the last fifty thousand, must have been less than the 50*s.* for which they are sold. The difference between the price and the cost of production is *rent.* It is an advantage derived from the use of a natural agent not universally accessible. It is taken, therefore, by the owner of the agent by whose assistance it was obtained.

A portion of the whole supply, however, that portion which is produced at the greatest expense, is produced without any payment of rent. If the cost of producing and sending to market from a given farm be in the following proportions: for one hundred quarters £1000, for ninety more £100, for eighty more £100, for seventy more £100, for sixty more £100, for fifty more £100, for forty more £100, and for thirty-three and one-third of a quarter more £100, and the price per quarter is 60*s.*, it is clear that the landlord's rent will be in the following proportions:

On the first	£100 expended	£200
On the second	100	170
On the third	100	140
On the fourth	100	110
On the fifth	100	80
On the sixth	100	50
On the seventh	100	20
	In all	£770

And it is equally clear that no rent can be paid by the farmer for the privilege of producing the last thirty-three one-third quarters, as the whole £100 for which it sells is absorbed by the cost of production. The last thirty-three one-third quarters will continue to be produced as long as the wants and the wealth of the purchasers render them willing and able to purchase a quantity of corn, the whole of which cannot be supplied unless this last and most expensive portion is produced. If those wants and wealth should increase, it might become necessary to raise an additional supply at a still further additional expense, at the cost, we will say, of £100 for only twenty quarters. But it is clear that this could not be done unless the price should be £5 a quarter, since that is the lowest price at which the cost of producing the last supply would be repaid. The price, indeed, would probably have previously risen to above £5 a quarter, since an interval must have elapsed between the increased demand occasioned by the increased wants and wealth of the purchasers and the increase of the supply. During that interval the price must have risen somewhat above the price at which it would settle when the additional supply had been obtained. The appearance of that additional supply would sink it to £5 a quarter, the cost at which that supply is produced, but it could not permanently fall below that price unless a diminution should take place either in the wants or wealth of the purchasers, or in the expenses of cultivation or conveyance.

All this appears almost too plain for formal statement. It is however one of the most recent discoveries in Political Science: so recent that it can scarcely be said to be universally admitted even in this Country, and that abroad it does not seem to be even comprehended. If any writer could be expected to be fully master of it it would be Say, the most distinguished of the Continental Economists, and the annotator on Ricardo. In his notes to the French translation of the *Principles of Political Economy and Taxation,* he constantly objects to Mr. Ricardo's reasonings, the fact that all cultivated land pays rent; as if such a fact were inconsistent with the existence of corn raised without the payment of rent. He repeats this objection in a note to a passage in which Ricardo has demonstrated its falsity. In the twenty-fourth chapter of the *Principles*, Mr. Ricardo examines Adam Smith's opinions on rent.

" Adam Smith," observes Mr. Ricardo, " had adopted the notion that there were some parts of the produce of land for which the demand must always be such as to afford a greater price than what is sufficient to bring them to market; and he considered food as one of those parts.

" He says that ' land in almost every situation produces a greater quantity of food than what is sufficient to maintain all the labour necessary for bringing it to market, in the most liberal way in which labour is ever maintained. The surplus, too, is always more than sufficient to replace the stock which employed that labour, together with its profits. Something, therefore, always remains for a rent to the landlord.'

" But what proof does he give of this? No other than the assertion that ' the most desert moors in Norway and Scotland produce some sort of pasture for cattle, of which the milk and the increase are always more than sufficient not only to maintain all the labour necessary for tending them, and to pay the ordinary profit to the farmer or owner of the herd or flock, but to afford some small rent to the landlord.' Now of this I may be permitted to entertain a doubt. I believe that as yet in every Country, from the rudest to the most refined, there is land of such a quality that it cannot yield a produce more than sufficiently valuable to replace the stock employed on it, together with the profits ordinary and usual in that Country. In America we all know that this is the case, and yet no one maintains that the principles which regulate rent are different in that Country and in Europe. But if it were true that England had so far advanced in cultivation, that at this time there were no lands remaining which did not afford a rent, it would be equally true, that there formerly must have been such lands; *and that whether there be or not, is of no importance to this question, for it is the same thing if there be any capital employed in Great Britain on land which yields only the return of stock with its ordinary profits, whether it be employed on new or old land.* If a farmer agrees for land on a lease for seven or fourteen years, he may propose to employ on it a capital of £10.000, knowing that at the existing price of grain and raw produce he can replace that part of his stock which he is obliged to expend, pay his rent, and obtain the general rate of profit. He will not employ £11,000 unless the last £1000 can be employed so productively as to afford him the usual profits of stock. In his calculation whether he shall employ it or not, he considers only whether the price of raw produce is sufficient to replace his expenses and profits, for he knows that he shall have no additional rent to pay. Even at the expiration of his lease his rent will not be raised; for if his landlord should require rent, because this additional £1000 was employed, he would withdraw it, since by employing it he gets by the supposition, only the ordinary and usual profits which he may obtain by any other employment of stock." *Principles, &c.*, 389—391.

To this passage, M. Say affixes the following note: "This is precisely what Adam Smith does not admit, since he says that the worst land in Scotland gives to its proprietor a rent." We answer to M. Say: "This is precisely what Mr. Ricardo declares to be immaterial, since a portion of what is produced on a farm giving a rent of ten guineas an acre, may be produced without any rent being paid for the privilege of producing it."

It must be admitted, however, that the doctrine in question has often been stated in a form likely to confuse the dull or inattentive, and liable to the cavils of the uncandid. Mr. Ricardo, who, though not its discoverer, is its best known expositor, was led, both by his merits and his deficiences, into frequent inaccuracy of language. He was not enough master of logic to obtain precision, or even to estimate its importance. His sagacity prevented his making sufficient allowance for the stupidity or carelessness of his readers; and he was too earnest a lover of truth to anticipate wilful misconstruction.

Under the influence of these causes he is, perhaps, the most incorrect writer who ever attained philosophical eminence; and there are few subjects on which he has been guilty of more faults of expression than on rent.

He perceived that an increased will and power on the part of the community to purchase raw produce, and the impossibility of increasing the supply but at an increased expense, must necessarily raise rents, and must also occasion an extension of cultivation. Associating, therefore, in his own mind the ideas of the rise of rents and of the extension of cultivation, he has often spoken of them as if they stood in the relation of cause and effect: as if the extension of cultivation were a cause of the rise of rent, instead of being, as it obviously is, a means by which that rise is counteracted. The inaccuracy is so obvious that we can scarcely suppose it to have misled any reader of tolerable care and acuteness.

He has also too frequently used the expression "the corn raised *on land* paying no rent," as an equivalent for "the corn raised without the payment of rent." And when his opponents reply, as is true, that "in old Countries all land pays a rent," he has sometimes denied the truth of the reply, instead of showing, as he has done in the passage which we have quoted, that the doctrine is just as true when applied to a small district in which all the land is highly rented, as when applied to a colony where rent is the exception and freedom from it the rule.

Again, he has often spoken of the existence of rent as dependent on the cultivation of land of different degrees of fertility, or on the fact that the same land repays, with a proportionably smaller return, the application of additional capital. And yet it is clear that if we suppose the existence of a populous and opulent district of great but uniform fertility, giving a large return to a given expenditure of capital, but incapable of giving any return whatever on a less expenditure, or any greater return on a larger expenditure, such a district would afford a high rent though every rood of land and every portion of the capital applied to it would be equally productive.

We now proceed to consider some remarkable consequences of the proposition that additional labour when employed in manufactures is more, and when employed in agriculture less efficient in proportion; or, in other words, that the efficiency of labour increases in manufactures in an increasing ratio, and in agriculture in a decreasing ratio. And, consequently, that every additional quantity of manufactured produce is obtained, so far as the manufacturing it is alone concerned, at a less proportionate cost, and every additional quantity of agricultural produce is obtained, generally speaking, at a greater proportionate cost.

Different effects of increased demand on manufactured and raw produce.

So far as the price of any commodity is affected by the value of the new material of which it is formed, it has a tendency to rise, so far as the price consists of the remuneration to be paid for the labour and abstinence of those employed in manufacturing it, it has a tendency to fall, with the increase of population.

It is obvious that commodities of rude or simple workmanship are subject to the first rule, and the finer manufactures to the second. Bread may afford an instance of the first kind, and lace of the second. The average price in England of a half-peck loaf is now about 1*s.* 3*d.* Of this sum 10*d.*, at least, may be assumed to be the price of the wheat; the wages and profit of the miller, baker, and retailer absorbing the remainder. If circumstances should arise, requiring the present supply of bread to be immediately doubled from our home-produce, it is obvious that the increased supply of wheat could not be obtained by merely doubling the amount of labour now employed in its production. It is impossible to say to what amount the increased difficulty of production would raise the price of wheat; we will, however, suppose it to be doubled, and the price of the wheat necessary to make a half-peck loaf to be 1*s.* 8*d.* instead of 10*d.*: at the same time the increased labour employed in its manufacture and sale would become more efficient. The miller and the baker would employ better instruments and a greater division of labour, and the retailer would be able to double his sales at little additional expense. The price of bread, so far only as its manufacture and retail is concerned, would be reduced perhaps one-fourth, or from 5*d.* to 3¾*d.* In which case, the whole result of the increased production would be that the half-peck loaf would sell for 1*s.* 11¾*d.* instead of 1*s.* 3*d.*

We will now see what would be the effect of an increased use of lace.

At the present price of lace and cotton, a pound of cotton worth, in the Liverpool-market, 2*s.*, may be converted into a piece of lace worth 100 guineas. Suppose the consumption of lace to double, and the increased difficulty of producing the additional quantity of the cotton fit for lacemaking to raise its price from 2*s.* to 4*s.* a pound; the price of the lace, supposing it still to be manufactured at the same expense, would be raised one thousand and fiftieth part, or from £105 to £105 2*s.* But it is impossible to doubt that the stimulus thus applied to the production of lace would improve every process of the manufacture. We should probably much underrate the amount of that improvement if we were to estimate the consequent saving of expense at one-fourth; in which case the whole result of the increased production would be that the lace would sell for £78 17*s.* instead of £105; the same circumstances which would nearly double the price of bread would reduce by one-fourth the price of lace.

Another inference from the proposition in question is the difference between the effects of taxation when imposed on raw produce and when imposed on manufactured produce.

Different effects of taxation on manufactured and raw produce.

Taxes on manufactured commodities ultimately raise the price, and that by an amount exceeding the amount of the tax. Taxes on agricultural produce in its unmanufactured state do not necessarily occasion any ultimate rise of price, and raise it, if at all, by an amount less than that of the tax.

Effect of taxation on manufactured produce.

The first proposition may be easily illustrated.

We will suppose a tax on watches of twenty-five per cent. on their value to have existed from the commencement of that trade. As there is no reason to suppose that the profits or the wages of master watchmakers or their workmen are, under present circumstances, above the average wages and profits of persons similarly employed, it is clear that, if such a tax had always existed, the price for the time being of watches must always have been one-fourth higher than it has been, or the trade of watchmaking would have been followed neither by labourers nor capitalists. It is clear also that such an increase of price must always have diminished or retarded in its increase the sale, and, consequently, the production of watches. But if fewer watches had been made, the smaller number would have been made at a greater proportionate expense. And the price of watches must have been higher than it actually has been, first by the amount of the tax, and secondly by the greater expensiveness of the more limited manufacture. It is equally clear that, after the removal of such a tax, the price of watches would sink, first by the amount of the tax removed, and secondly by the improvement in the manufacture consequent on an increased production. It is equally clear that, if such a tax were now for the first time to be imposed, the price of watches must rise, first by the amount of the tax, and secondly by the amount of the increased proportionate expense of making and selling the diminished quantity sold, or watchmaking would cease to be as profitable as the average of trades. It is clear, too, that the more the use of watches diminished the higher the price must eventually rise. If only ten new watches were made every year, they would probably cost £500 a-piece. If only one were made, it would probably cost little less than the whole price of the ten. It is true that these effects would not immediately follow either the imposition or the removal of the tax: an interval must in either case elapse, during which, the existing capital in the watchmaking trade continuing the same, the supply of watches would be neither increased nor diminished, and, consequently, the price but little affected. During this interval, both the wages and the profits of those engaged in that business would be unnaturally high, or unnaturally low, and they would not acquire their natural level until, in the case of the removal of the tax, a sufficient number of persons were educated to the business, or, in the case of the imposition of the tax, the number of persons educated to the business had been sufficiently diminished, to enable the supply of watches to be proportioned to the demand, at a price giving average profits and wages to the capitalists and labourers employed in their manufacture and sale.

Effect of taxation on agricultural produce.

But if agricultural produce were subjected to such a tax, relief would be afforded by precisely the same conduct which in manufactures aggravates the pressure, namely, by a diminution of production.

It may be assumed that capital is fairly distributed among the various channels for its employment, and that, in the absence of peculiar disturbing causes, agriculture, the most agreeable of all occupations, has not less than an average share of it. It may therefore be assumed, generally speaking, that capital is employed on land until its produce repays, but does not more than repay, the expense of cultivation; or, in other words, that the occupier of land pushes its cultivation until the additional produce obtained by means of the last labourers employed is just sufficient, at the existing price, to pay their wages, and average profits to himself, for the time during which those wages must be paid in advance. On the imposition of a tax, either the price of what he produces must rise by the amount of the tax, or the farmer must discontinue the production of that portion of his crop which is raised at the greatest expense.

Effect of taxation on agricultural produce.

We will suppose a farmer to occupy a farm containing six hundred acres of arable land of different degrees of fertility; one hundred acres of which, with the labour of ten men directly and indirectly employed on them, would give a return which, in order to reduce it to one denomination, we will call six quarters of wheat an acre; one hundred others capable of giving with an equal number of men only five quarters per acre; one hundred others, four quarters per acre; one hundred others, three quarters per acre; one hundred others, two quarters per acre; and the last and worst one hundred acres, only one quarter per acre. We will suppose, also, that the wages of ten men for a year amount at an average to £400, or £40 a man; that the farmer has to advance these wages for a year before the produce is sold; and that the average rate of profit in similar occupations, is ten per cent. per annum. Under such circumstances, when wheat was £2 4*s*. a quarter it would be worth his while to employ every man whose labour produced twenty quarters, the price of which would amount to £44, being £40 for the labourer's wages, and £4 for the farmer's profit. The forty men supposed to be employed on the four best qualities of soil produce each this amount and more; the ten men employed on the fifth quality of soil produce each precisely this amount, namely, a return of two hundred quarters, worth £440. The sixth and last quality of soil, on which one man could produce only ten quarters, would not repay the cultivation of wheat. Now, if a tax were laid on raw produce, which, to make the illustrations less complex, we will call a tax of 14*s*. 8*d*. on every quarter of wheat, and no rise of price should take place, it is obvious that it would no longer be worth his while to cultivate any land of worse quality than that in which the labour of ten men could produce three hundred quarters of corn; a return which, at the existing price of £2 4*s*. a quarter, would procure £660, being £220 for the tax, and £440 as before for wages and profits. But it would obviously be worth his while to cultivate land of that quality, and also to employ labour in the cultivation of his superior land up to the point of which the labour of an additional man would no longer produce an additional produce of thirty quarters. Nothing but a tax so great as absolutely to prohibit agriculture, such a tax as never has existed, and which would, in fact, be rather a penalty than a tax, could induce him to discharge all his labourers, and leave his best land uncultivated. We do not deny that he would be a loser, even by the conduct which we have supposed him to adopt. We do not deny that he would much have preferred a rise in the price of corn equal to the tax,—a rise which would have enabled him to continue in its existing investment all his agricultural capital. But we deny that any imposition to which the name of a tax can fairly be applied, though unaccom-

Distribution. Effect of taxation on agricultural produce.

panied by a rise of price, would induce him altogether to discontinue production. And we wish to draw the attention of our readers to the contrast between his situation and that of the manufacturer, whom any tax, however slight, if unaccompanied by a rise of price, must in time force to discontinue manufacturing. What is a remedy to the agriculturist is an aggravation of evil to the manufacturer; a diminution of capital makes what remains in agriculture more productive, and makes what remains in manufactures less so.

It has been supposed, however, that the price of agricultural produce would rise to the full amount of the tax, and that the whole amount of that tax would consequently fall on the consumer. This is the opinion of Mr. Ricardo and of Mr. Mill. And it is on this ground that they both maintain that the effect of tithes is to produce a rise in the price of raw produce equal to the whole value of the tithe, and affecting equally all classes so far as they are consumers of raw produce. We believe that the *immediate* effect of a general tax on raw produce is to raise its price, but to an amount not equal to that of the tax; but that its *ultimate* effect is to diminish the consumption and production of raw produce, but to leave its price unaffected

To prove our first proposition we need only show that the rise of price, which we admit to be the immediate consequence of the imposition of the tax, would diminish the consumption, and consequently the production of the taxed commodity. It has been shown already that, as production is diminished, the expense of producing the quantity still produced is diminished; and that the price of agricultural produce depends on the expense of producing that portion of it which is produced at the greatest expense, or, in other words, under circumstances of equal competition. That no person would diminish his consumption of corn in consequence of the rise of its price, is therefore a premise necessary to the conclusion which we are combating. This is true as respects that portion of the population of England which is dependent on parochial relief. In those districts in which the amount of that relief is calculated with reference to the price of bread, their means of purchasing are unconnected with price, and neither rise with its fall nor sink with its rise. It is true, also, as respects the families of those opulent individuals (a prominent, but in fact a small portion of society) whose direct expenditure in bread and flour bears a small proportion to their general expenses. But the bulk of the community, consisting of the labourers who receive no parish assistance, and happily they are now the majority, and we trust will soon be the great majority; and the smaller shopkeepers and farmers, unquestionably regulate, in a great measure, their purchases of wheat by its price. Much of their consumption, when it is comparatively cheap, consists of puddings and pies, articles of mere luxury, which, on the slightest rise, are immediately discontinued. If the rise continue, they turn from wheaten bread to cheaper subsistence: in the North to oatmeal, in the South to potatoes. And, indeed, without recurring to details, it may be laid down as a principle of universal application, that, in the absence of disturbing causes, every increase in the price of a commodity must diminish both the ability and the will to purchase it.

We now proceed to prove our second proposition, namely, that the ultimate effect of a tax on raw produce is not to raise its price, but to diminish the quantity produced. It will be at once admitted that the price of raw produce, in any Country, does not depend on the positive extent, or on the positive fertility of that Country, but, all the other things remaining the same, on the proportion which that extent, or that fertility bears to the number and wealth of the existing inhabitants. It may be low in a barren territory, if that territory be thinly peopled, just as it may be high in a fertile and populous one. It is high in the rich Lowlands of Scotland, and low in the sandy plains of Poland. And it will also be admitted that, all other things remaining the same, the population of a Country is in proportion to its extent and its fertility. Now, the ultimate effect of tithes, or of any other tax, on the cultivation of land is precisely the same as if the Country in which they have long prevailed were thereby rendered rather less extensive, or rather less fertile, and consequently, rather less populous, and probably also rather poorer than it otherwise would have been.

If England, from time immemorial, had been rather more extensive, or rather more fertile than it now is, no one will suppose that the price of provisions would have been lower than it now is. We should have had rather more corn, and a rather greater population to eat that corn, than we now have. The increase would have been positive, not relative. So if Devonshire or Lincolnshire had never existed, the agricultural produce and the population of England would each have been positively diminished; but, as they would have borne the same proportion to one another as they do now, the price of the existing quantity of corn could not have been higher than it is now. So if tithes had never existed, we should have had rather more corn, and a rather larger and probably a rather richer population; every thing else would have been as it is. It is true that, if a new Devonshire, or a new Lincolnshire, fit for immediate cultivation, were now suddenly added to our shores, the immediate consequences would be, an increased supply of provisions, and a fall in their price. But it is also true that, if this accession to our territory were followed by no change in our habits and institutions, the comparative cheapness, which would be its immediate consequence, would gradually disappear as our population rose with the increased supply of subsistence, and, ultimately, we should be just where we are now, excepting that we should be rather more numerous. So, if tithes were suddenly commuted, and their interference, such as it is, with agricultural improvement, got rid of, the same consequences would follow as if the extent of our territory, or its fertility were suddenly augmented. And, supposing no improvement to take place in our institutions and habits, the consequent increase of our population would bring us back, as far as the price of provisions is concerned, to the point at which we are now.

It is probable, indeed, that the ultimate effect of the abolition of tithes would be not a lowering but an increase of the price of raw produce. A denser population cultivating a territory, the productiveness of which had increased in proportion to the increased number of its inhabitants, would probably advance in opulence. The productiveness of the soil of a Country in proportion to its population being given, or, in other words, the amount of raw produce and the number of people being ascertained, the smaller the extent of the land from which that amount is obtained the better. The expenses of transport, and the trouble and loss of time in journeys, are material elements of the cost of production both in agriculture and in manufactures, and the amount of these expenses depends principally on the

Distribution. Effect of taxation on agricultural produce

extent of Country affording a given return. As our industry became more efficient the value of our labour would rise in the general market of the world, and the consequence would be a general rise of prices, in which agricultural produce would participate. But these statements form no part of our argument. We believe, indeed, that the ultimate effect of tithes is to lower the price of raw produce: but all that we have undertaken to show is, that they do not raise it.

From these premises follow very important practical inferences. If we lay a tax on the production at home of any manufactured commodity which is produced with the same, or nearly the same, facility abroad, it is absolutely necessary that a duty of the same, or a rather greater amount, should be imposed on the importation of that commodity. On the imposition of the tax the cost of production at home is increased, first by the tax, and secondly by the increased expense of producing the smaller quantity which, when the price becomes higher, continues to be demanded. But if importation were untaxed, the cost of production abroad would be diminished in consequence of the diminished proportionate expense of producing the larger quantity demanded. The domestic production, and with the domestic production the tax, would not be merely diminished, but absolutely destroyed, and the whole result would be gratuitous evil. But when a tax, unbalanced by any countervailing duty on importation, is imposed on any agricultural produce for which a foreign substitute can be obtained, the only result is to stop *that portion which is most expensive* of the domestic production. The least productive part of the existing agricultural capital is withdrawn, or worn out without being replaced. The deficiency is attempted to be supplied by importation; but the increased demand instead of lowering, as would be the case with manufactures, raises the cost of production abroad, just as the diminished demand, instead of raising, lowers the cost of production at home. The price of agricultural produce rises until the state of the population has accommodated itself to the change, and then falls to its former level. If our present heavy tax on the domestic production of glass were unbalanced by any duty on importation, all the English glass-works would in time be abandoned. Or, if some of our glass-works were free from the tax, and others subject to it, all those which were taxed would be ruined. But the lands in England which are subject to the payment of tithes are not thrown out of cultivation by the competition of those which are free from that burden, or by the importation of the tithe-free corn and cattle of Scotland, or of the comparatively tithe-free produce of Ireland. The estates which are subject to tithes continue to be productive, they continue even to afford a rent, though the burden diminishes the productiveness, and diminishes in a still greater degree the rent.

Before we quit the subject of tithes, it may be worth while to expose another error connected with them, namely, the popular opinion that their tendency to increase in amount is greater than that of rent. We believe the fact to be just the reverse.

Tithes are a definite, rent is an indefinite, share of the produce. Tithes can never exceed a tenth; rent need not be a tenth, or even a hundredth, but may amount to a fourth, a third, a half, or even more than a half. Tithes, therefore, can be exacted, where rent cannot be; but when once any spot of land can afford to pay both rent and tithes, there is no comparison between their respective powers of increase. This will immediately appear on a reference to the familiar illustration of the progress of rent.

If we suppose a Country to be divided into ten districts designated by the numbers from 1 to 10, each of equal extent, but each of a different degree of fertility, No. 1 producing, at a given expense, two hundred quarters of corn, and the amount of the produce, at the same expense, of each quality of land, diminishing by ten quarters until we come to No. 10, which produces only one hundred quarters, we shall find that when No. 1 only will pay for cultivation, it affords twenty quarters for tithes, and no rent. When the price of corn has risen sufficiently to enable No. 2 to be cultivated, there will be on Nos. 1 and 2 thirty-nine quarters for tithes, and on No. 1 ten for rent. When No. 3 has become worth cultivation, there will be on Nos. 1, 2, and 3, fifty-seven for tithes, and on Nos. 1 and 2 thirty for rent. When No. 4 has become worth cultivating, there will be on Nos. 1, 2, 3, and 4, seventy-four for tithes, and on Nos. 1, 2, and 3, sixty for rent. When No. 5 has become worth cultivating, there will be on Nos. 1, 2, 3, 4, and 5, ninety for tithes, and on Nos. 1, 2, 3 and 4, one hundred for rent. Rent has now passed tithes, and its subsequent superiority is very striking. When No. 6 has become worth cultivating, there will be one hundred and five for tithes, and one hundred and fifty for rent. When No. 7 has become worth cultivating, there will be one hundred and nineteen for tithes, and two hundred and ten for rent. When No. 8 has become worth cultivating, tithes will be one hundred and thirty-two, and rent two hundred and eighty. When No. 9 has become worth cultivating, tithes will be one hundred and forty-four, and rent three hundred and sixty. And when No. 10 has become worth cultivating, tithes will be one hundred and fifty-five, and rent four hundred and fifty. And the same results will follow if, instead of supposing fresh land of a regularly decreasing fertility to be taken into cultivation, we suppose further capital to be applied to the same land, with a regularly decreasing proportionate return. Of course we do not mean that either of these suppositions represents what actually takes place, but they each represent the course of events to which there is a natural tendency. They represent the relative ratio at which rent and tithes would increase in the absence of disturbing causes. It must be recollected, however, that these events would not take place in the regular order in which we have placed them, except on the supposition of each different district which we have supposed to be successively cultivated being of the same extent, and of each successive application of capital being of the same value. If, for instance, No. 10 were ten times as large as any one of the other districts, and received ten times as much capital, it would increase the whole amount of titheable produce by one thousand quarters instead of by one hundred quarters, and tithes would be raised from one hundred and forty-four quarters to two hundred and forty-four quarters, while rent would have risen only from three hundred and sixty quarters to four hundred and fifty. In such an event, therefore, tithes would rise more than rent. And it must also be recollected that tithes and rent do not rise at precisely the same period. The highest amount of rent must be just *before* the land producing the additional supply has been cultivated. The increased demand is then in full operation, and has not been counteracted by the increased supply. But the amount of tithes is not increased until *after* the additional supply has been produced. Their increase, therefore, is generally contemporaneous with a temporary fall of rent: which is probably one of the causes of the popular opinion that their general tendency to increase is greater than that of rent. Another source of that opinion is, that in England the land has been for centuries subject to a constant process of subdivision, while tithes, except the comparatively small part which belongs to laymen, have not. The incumbent of a given benefice receives the tithes of the same quantity of land which was tithed by his predecessor three hundred years ago. But that land three hundred years ago may have belonged to one or two persons, and may now be divided between ten or twenty. The present incumbent's income may bear a higher proportion than his predecessor's did to the average income of a single landlord, though it bears a lower proportion to the aggregate income of all the landlords of the parish. And as a general proposition, we have no doubt that, in a progressive Country, the value of tithes will seldom increase in proportion to the increasing value of the land out of which they issue.

It appears, therefore, that in a new or ill-peopled Country where the abundance of land and the want of agricultural capital almost prevent the existence of rent, in the economical sense of the word, tithes are the only endowment which a Clergy can receive from the soil. We see, therefore, why they were adopted for the Israelites, who, in fact, were colonists, and by our Danish and Saxon ancestors. We see too why the attempt to endow with lands the Canadian Church has so signally failed. Tithes would not, perhaps, have been a politic, but they would have been an actual endowment. The reserves stand so many desert spots in the midst of improvements retarding the settlement, interrupting the communications, and injuring the wealth and civilization of all that is round them. Five centuries hence they might afford an ample provision.

Relative Proportions of Rent, Profit, and Wages.

Proportions of rent, profit, and wages. Nomenclature.

Having given a general outline of the three great classes among whom all that is produced is distributed, and of the general laws which regulate the comparative values of different products, we now proceed to consider the general laws which regulate the proportions in which landlords, capitalists, and labourers share in the general distribution, or, in other words, which regulate the proportions which rent, profit, and wages bear to one another.

We have followed the established nomenclature which divides society into landlords, capitalists, and labourers; and revenue into rent, wages, and profit. And we have defined rent to be the revenue spontaneously offered by nature or accident; wages the reward of labour; and profit that of abstinence. At a distance these divisions appear clearly marked, but when we look into the details, we find them so intermingled that it is scarcely possible to subject them to a classification which shall not sometimes appear to be inconsistent, and still more frequently to be arbitrary. But it must be remembered that questions of classification relate rather to language than to facts; and that our object will have been effected if we can assist the memory by supplying a precise and consistent nomenclature.

We will begin by recurring to a subject to which we have already alluded, the frequent difficulty of deciding whether a given revenue ought or ought not to be called rent. When an estate has been for some time leased to a careful tenant, it generally receives permanent ameliorations, which enable the owner, at the expiration of the lease, to obtain a higher rent. A bog worth 2*s.* annually an acre may be converted into arable or pasture worth annually £2. Is the increase of revenue rent or profit? It arises from an additional fertility, now inseparably attached to the land. It is received by the owner without sacrifice on his part. It is, in fact, undistinguishable from the previous rent. On the other hand, its existence is owing to the abstinence of the farmer, who devoted to a distant object, the amelioration of the land, labour which he might have employed in producing immediate enjoyment for himself. If the owner of the estate had farmed it himself, and had directed labour to be employed on its permanent improvement, the additional produce occasioned by those improvements would clearly have been termed profit. It appears, therefore, most convenient to term it profit when occasioned by the improvements made by a tenant.

In fact, these improvements are as consistently to be termed capital as a dock or a cotton-mill. Whose capital are they then? During the lease the capital of the tenant; when it has fallen in, the capital of the landlord, who has purchased them by engaging not to raise the rent during the currency of the lease.

We may be asked, then, whether the improvements which form the greater part of the value of the soil of every well-cultivated district are all, and for ever, to be termed capital? Whether the payments received from his tenants by the present owner of a Lincolnshire estate, reclaimed by the Romans from the sea, are to be termed, not rent but profit on the capital which was expended fifteen centuries ago? The answer is that, for all useful purposes, the distinction of profit from rent ceases as soon as the capital, from which a given revenue arises, has become, whether by gift or by inheritance, the property of a person to whose abstinence and exertions it did not owe its creation. The revenue arising from a dock, or a wharf, or a canal is profit in the hands of the *original constructor*. It is the reward of *his* abstinence in having employed capital for the purposes of production instead of for those of enjoyment. But in the hands of his heir it has all the attributes of rent. It is to him the gift of fortune, not the result of a sacrifice. It may be said, indeed, that such a revenue is the reward for the owner's abstinence in not selling the dock or the canal and spending its price in enjoyment. But the same remark applies to every species of transferable property. Every estate may be sold, and the purchase-money wasted. If the last basis of classification were adopted, the greater part of what every Political Economist has termed rent must be called profit.

Again, there are few employments in which extraordinary powers of body or mind do not receive an extraordinary remuneration. It is the privilege of talent to work not only better but more easily. It will generally be found, therefore, that the commodity or service produced by a first-rate workman, while it sells for more than an average price, has cost less than an average amount of labour. Sir Walter Scott could write a volume with the labour of about three hours a day for a month, and for so doing received £500 or £1000. An ordinary writer, with equal application, would find it difficult to produce a volume in three months, and still more difficult to sell it for £50.

Is then the extraordinary remuneration of the labourer, which is assisted by extraordinary talents, to be termed rent or wages? It originates in the bounty of nature; so far it seems to be rent. It is to be obtained only on the condition of undergoing labour; so far it seems to be wages. It might be termed, with equal correctness, rent, which can be received only by a labourer, or wages, which can be received only by the proprietor of a natural agent. But as it is clearly a surplus, the labour having been previously paid for by average wages, and that surplus the spontaneous gift of nature, we have thought it most convenient to term it rent. And for the same reason we term *rent* what might, with equal correctness, be termed fortuitous profit. We mean the surplus advantages which are sometimes derived from the employment of capital after making full compensation for all the risk that has been encountered, and all the sacrifices which have been made, by the capitalist. Such are the fortuitous profits of the holders of warlike stores on the breaking out of unexpected hostilities; or of the holders of black cloth on the sudden death of one of the Royal family. Such would be the additional revenue of an Anglesea miner, if, instead of copper, he should come on an equally fertile vein of silver. The silver would, without doubt, be obtained by means of labour and abstinence; but *they* would have been repaid by an equal amount of copper. The extra value of the silver would be the gift of nature, and therefore rent.

Secondly. It is still more difficult to draw the line between profit and wages. There are, perhaps, a few cases in which capital may improve in value, without superintendence or change, simply by being preserved from consumption. Wine and timber, perhaps, afford instances. But even a wine-cellar or a plantation, if totally neglected, would probably deteriorate. And, as a general rule, it may be laid down that capital is an instrument which, to be productive of profit, must be employed, and that the person who directs its employment must *labour*, that is, must to a certain degree conquer his indolence, sacrifice his favourite pursuits, and often incur other inconveniences from his residence, from the persons to whose contact he is exposed, from confinement or from exposure to the weather, and must also often submit to some inferiority of rank. If labour be in general necessary to the use of material capital, it is universally necessary to the use of that immaterial capital which consists of appropriate knowledge, and of moral and intellectual habits and reputation.—A capital created and kept up at more expense, and productive of a greater return than that which is material, but which, from the impossibility of actually transferring it, or implanting in one man the ability of another, can never be productive but through the labour of its possessor.

Is then the remuneration of this labour to be termed wages or profit? A certain portion of it, that portion which would be sufficient to repay equal exertions and hardships endured by an ordinary labourer, unprovided with capital, must, without doubt, be termed wages. And where extraordinary natural talents or favourable accidents have occasioned the exertions of the capitalist to obtain more than an average remuneration, that excess is, as we have already seen, rent. But the revenue to which our present question applies is the revenue obtained from the employment of capital, after deducting ordinary interest on the capital, as the remuneration for the abstinence of the capitalist, ordinary wages, as the remuneration for his labour, and any extraordinary advantages which may have been the result of accident.

The subject may be made clearer by a few examples; and we have endeavoured to find some in which the remuneration for the capitalist's trouble, instead of being, as is usually the case, mixed up with the gross amount of his returns, appears as a separate item. The trade of bill-broking affords an instance. The business of a bill-broker is to advance, before it becomes due, the money for which bills of exchange are drawn, deducting, under the name of discount, interest at the rate of not more than five per cent. per annum on the sum secured by the bill. In time of peace, and in the ordinary state of the money-market, the rate of discount varies from four to three per cent. per annum. It has been sometimes as low as two and a half. It appears at first strange that such a trade should exist, since the money capital employed in it does not return even so high a profit as may often be obtained from the public funds, leaving the additional risk and labour uncompensated. It is, in fact, a trade which no one *would* carry on if he employed in it his own money.

The commercial inhabitants of a great trading city have from time to time under their control considerable sums of money for short periods. Scarcely a single estate in this Country is mortgaged or sold without the price or the mortgage-money being placed for some days at a banker's or agent's until the "more last words" of the lawyers have been said. These sums cannot in the mean time be employed in any permanent investment; but they can be lent from day to day, or, in some cases, from week to week, and it is better to lend them at the lowest rate of interest than to suffer them to lie perfectly idle. The bill-broker's trade is to borrow these sums from week to week, or even from day to day, at one rate of interest, and to lend them from month to month, or for two or three months, at a higher. To borrow, for instance, at two per cent. and to lend at three.

It is obvious that these operations require much knowledge, industry, and skill. The broker must be well acquainted with the circumstances of almost every eminent commercial man in order to estimate the value of his acceptance or indorsement. He must keep up his knowledge by unremitting observation, and by inferences drawn from very slight hints and appearances. He must also have the skill so to manage his concerns as to have his receipts always falling in to correspond with his engagements. This knowledge, and the moral and intellectual habits which enable him to apply it, form his personal or immaterial capital. But he must also have a material capital, not for the purpose of being employed in his business, for no one would so employ money of his own, but as the means of obtaining confidence. The interest paid by a broker is so trifling that no one would lend to him if it implied the slightest risk; and the best pledge which he can give is the notoriety of his possessing a large capital, which could at any time make good an unforeseen interruption in his regular receipts. This capital he must not waste, but he may employ it productively, and may consume on himself the annual profit derived from it. The confidence which it enables him to enjoy is a distinct advantage.

We will suppose a bill-broker to possess £100,000 in the Four per Cents; and to have sufficient knowledge, skill, and character as a man of business and of wealth, to be able, at an average throughout the year, to borrow

£400,000 at two per cent., and to lend the same sum at three per cent. Is the £4000 a year which his business would give him wages or profit?

Again, a capital which in this Country would enable its employer to obtain ten per cent., would often, if he were to employ it in Jamaica or Calcutta, produce fifteen or twenty. If the capitalist with £50,000 encounter the climate and the society of Jamaica, and is rewarded by his annual returns being raised from £5000 to £7500, is his additional income of £2500 a year wages or profit?

There is no doubt that a sufficient portion of it to purchase the same services from a person unprovided with capital, must be considered as wages: £500 a year, however, would considerably exceed this sum. The remaining £2000 a year may be considered, with equal correctness, either wages which can be received only by the possessor of £50,000, or profit which can be received only by a person willing to labour in Jamaica.

Adam Smith considers it as profit. "The profits of stock," he observes,* "it may, perhaps, be thought, are only a different name for the wages of a particular sort of labour, the labour of inspection or direction. They are, however, altogether different, are regulated by quite different principles, and bear no proportion to the quantity, the hardship, or the ingenuity of this supposed labour of inspection and direction. They are regulated altogether by the value of the stock employed, and are greater or smaller in proportion to this stock. If we suppose two manufacturers, the one employing a capital of £1000 and the other one of £7300, in a place where the common profits of manufacturing stock are ten per cent., the one will expect a profit of about £100 a year, while the other will expect about £730. Yet their labour of inspection may be very nearly or altogether the same. In many great works, almost the whole labour of this kind is committed to some principal clerk. His wages properly express the value of this labour of inspection and direction. Though in settling them some regard is commonly had, not only to his labour and skill, but to the trust which is reposed in him, yet they never bear any regular proportion to the capital of which he oversees the management. And the owner of this capital, though he is thus discharged of almost all labour, still expects that his profits should bear a regular proportion to his capital."

After much hesitation, we have resolved to adopt this as the most convenient classification, and to confine the term wages to the remuneration for simple labour; including under the word labour the endurance of all its attendant hardships, but excluding from the word wages the additional revenue which the labourer often receives because he happens to be also a capitalist. We have done so on the grounds which are so ably stated in the passage which we lastly quoted.

To revert to our supposition of a capitalist with £50,000 repaid by an extra revenue of £2500 a year for living in Jamaica: it is clear that another capitalist taking there £100,000 would, *cæteris paribus*, obtain an extra revenue of £5000 a year, and *that* notwithstanding his labour would not necessarily be greater than that of the first-mentioned capitalist, or notwithstanding it might in fact be much less. Perhaps the best plan might appear to be, to apply the term *wages* to the remuneration of mere labour, the term *interest* to the remuneration of mere abstinence, and the term *profit* to the combination of wages and interest, to the remuneration of abstinence and labour combined. This would make it necessary to subdivide capitalists into two classes, the inactive and the active: the first receiving mere interest, the second obtaining profit.

In this, however, as in many other cases, the inconveniences occasioned by departure from an established nomenclature and an established classification are so great, that we do not think that they will be compensated by the nearer approach to precision. We shall continue, therefore, to include under the term profit the whole revenue that is obtained from the possession or employment of capital, after deducting those accidental advantages which we have termed rent, and also deducting a sufficient sum to pay to the capitalist, if actively employed, the wages which would purchase an equal amount of labour from a person unpossessed of capital. In one respect, however, we are forced to differ from Adam Smith. Although he considers the useful, acquired knowledge and abilities of all the inhabitants of a Country as part of the national fortune, as a capital fixed and realized in the persons of their possessors, yet he generally terms the revenue derived from this capital *wages*. "The average and ordinary rates of profit in the different employments of stock are," he observes, "more nearly on a level than the wages of the different sorts of labour. The difference between the earnings of a common labourer and those of a well-employed lawyer or physician, is evidently much greater than that between the ordinary profits in any two different branches of trade." Book i. ch. x.

According to our nomenclature (and indeed according to that of Smith, if the produce of capital is to be termed profit) a very small portion of the earnings of the lawyer or of the physician can be called wages. Forty pounds a year would probably pay all the labour that either of them undergoes, in order to make, we will say, £4000 a year. Of the remaining £3960, probably £3000 may in each case be considered as rent, as the result of extraordinary talent or good fortune. The rest is profit on their respective capitals; capitals partly consisting of knowledge, and of moral and intellectual habits acquired by much previous expense and labour, and partly of connection and reputation acquired during years of probation while their fees were inadequate to their support.

Under this view of the case the revenue which consists of profit will in the progress of improvement bear a constantly increasing proportion to that which consists of wages. There appears no reason to doubt that, as civilization advances, every person will receive an education which will materially increase his power of production. Brutes and machinery can effect almost every thing that is to be effected by mere bodily exertion. Whatever requires mind, will be done better in proportion as the mind has received earlier or more judicious cultivation. We have heard it made a subject of complaint, that the uneducated Irish have dispossessed the English of the lowest employments in London and its neighbourhood. We rather rejoice that the English are sufficiently educated to be fit for better things. If they had remained as ignorant as their rivals, many who are now earning 40*s.* a week as mechanics, might have been breaking stones and carrying hods at 2*s.* a day. Even in our present state of civilization, which, high as it appears by comparison, is far short of what may easily be conceived, or even of what may confidently be expected, the intellectual and moral capital of Great Britain far exceeds all her material capital, not only in importance, but even in productiveness. The families that receive mere wages probably do not form a fourth of the community; and the comparatively large amount of the wages even of these is principally owing to the capital and skill with which their efforts are assisted and directed by the more educated members of the society. Those who receive mere rent, even using that word in its largest sense, are still fewer: and the amount of rent, like that of wages, principally depends on the knowledge by which the gifts of nature are directed and employed. The bulk of the national revenue is profit; and of that profit the portion which is mere interest on material capital probably does not amount to one-third. The rest is the result of personal capital, or, in other words, of education.

---

* Book i. ch. vi.

It is not on the accidents of soil or climate, or on the existing accumulation of the material instruments of production, but on the quantity and the diffusion of this immaterial capital, that the wealth of a Country depends. The climate, the soil, and the situation of Ireland have been described as superior, and certainly are not much inferior, to our own. Her poverty has been attributed to the want of material capital; but were Ireland now to exchange her native population for seven millions of our English North Countrymen, they would quickly create the capital that is wanted. And were England, North of Trent, to be peopled exclusively by a million of families from the West of Ireland, Lancashire and Yorkshire would still more rapidly resemble Connaught. Ireland is physically poor because she is morally and intellectually poor, because she is morally and intellectually uneducated. And while she continues uneducated, while the ignorance and violence of her population render persons and property insecure, and prevent the accumulation and prohibit the introduction of capital, legislative measures, intended solely and directly to relieve her poverty, may not indeed be ineffectual, for they may aggravate the disease, the symptoms of which they are meant to palliate, but undoubtedly will be productive of no permanent benefit. Knowledge has been called power; it is far more certainly wealth. Asia Minor, Syria, Egypt, and the Northern coast of Africa, were once among the richest, and are now among the most miserable Countries in the world, simply because they have fallen into the hands of a people without a sufficiency of the immaterial sources of wealth to keep up the material ones. "In what way," asks Adam Smith, "has Europe contributed to the grandeur of the colonies of America? In one way, and in one way only, she has contributed a great deal. *Magna virum mater.* She bred and formed the men who were capable of achieving such great actions, and of laying the foundation of so great an empire; and there is no other quarter of the world of which the policy is capable of forming, or has ever actually and in fact formed such men. The colonies owe to Europe the education and great views of their active and enterprising founders, and some of the greatest and most important of them owe to her scarce any thing else."

Proportionate Amount of Rent.

We have already defined rent to be the revenue spontaneously offered by nature or accident, or, in other words, to be the price paid for the assistance of an appropriated natural agent. It might with equal propriety be defined the surplus produce arising from the use of an appropriated natural agent, or the amount by which the price of the produce of an appropriated natural agent exceeds the costs of its production.

The nature and the progress of the rent of land have usually been illustrated by supposing lands of different fertility to be successively taken into cultivation. Thus the land No. 1 is supposed to afford, in return for the application of a given amount of labour and capital, one hundred quarters; No 2, ninety quarters; No. 3, eighty quarters; No. 4, seventy quarters; No. 5, sixty quarters; and so on. While any portion of the most fertile lands is unappropriated, No. 1 only is cultivated, and no rent is paid. Before it has become necessary to cultivate No. 2, No. 1 must have become an appropriated agent, affording a larger return than can be obtained without its assistance. Its owner, or, as he is termed, the landlord, obtains, therefore, the value of that assistance, being ten quarters, or the difference between one hundred quarters and ninety quarters; and receives it himself, in kind, if he himself is the cultivator, or is paid for it the remuneration termed "rent," if he allows another person to be the cultivator. Before it has become necessary to cultivate No. 3, the rent of No. 1 must have risen from ten quarters to twenty, and No. 2, from giving no rent, must have given a rent of ten quarters; and so on until the point is reached at which the labour and capital employed will produce a return only sufficient to give a bare subsistence to the labourer and average profits to the capitalist: the highest extreme to which cultivation can be intentionally pushed, and one, indeed, beyond which it is seldom carried.

It is obvious, therefore, that the amount of rent depends on two causes: 1. the positive productiveness of the natural agent by which it is afforded; 2. the comparative productiveness of that agent, or the degree in which it exceeds those agents which are universally accessible. If the supply of natural agents were unlimited, or if their power of affording assistance were to cease, in either case rent would be at an end. Rent is the value of their assistance, and that value, like all others, depends partly on their utility, and partly on their limitation of supply. Much error has arisen from attending to only one of these causes.

The French Economists* perceived that the produce

---

* *Le laboureur est le seul dont le travail produisse au delà du salaire du travail. Il est donc l'unique source de toute richesse.*

La terre, indépendamment de tout autre homme et de toute convention, lui paie immediatement le prix de son travail. La nature ne marchande point avec lui pour l'obliger à se contenter du nécessaire absolu.—Ce qu'elle donne n'est proportionnée ni à ses besoins ni à une évaluation conventionnelle du prix de ses journées. C'est le résultat physique de la fertilité du sol, et de la justesse, bien plus que de la difficulté des moyens, qu'il a employés pour le rendre fécond. Dès que le travail du laboureur produit au delà de ses besoins, il peut, avec ce superflu que la nature lui accorde en pur don, au delà du salaire de ses peines, acheter le travail des autres membres de la société. Ceux-ci en le lui vendant ne gagnent que leur vie, mais le laboureur recueille outre sa subsistence une richesse disponible; qu'il n'a point achetée, et qu'il vend. Il est donc l'unique source des richesses, qui, par leur circulation, animent tous les travaux de la société; parcequ'il est le seul dont le travail produisse au delà du salaire du travail.

Il reste donc constant qu'il n'y a de revenu que le produit net des terres, et que tout autre profit annuel, ou est payé par le revenu, ou fait partie des frais qui servent à produire le revenu.—Turgot vol. v. p. 8—9—126.

Vous ne pouvez trouver le meilleur état possible d'une nation, que dans la plus grande richesse possible. *J'entends ici par la terme de* richesse, *une masse de valeurs* disponibles, *de valeurs qu'on puisse*

of fertile land, the most important of all appropriated natural agents, sells for a price exceeding the expense of its cultivation. This excess of price, or *produit net*, as they termed it, they conceived to be the only source of wealth. All other commodities appeared to them merely to represent the toil employed in their acquisition. They believed, therefore, a community to be rich in proportion to the amount of rent received by the proprietors of its land; and consequently that production enriches only so far as it is subservient to the creation of rent.

It is impossible that they could have maintained this doctrine, if they had perceived that abundance is an element in wealth, and that high rents and the greatest abundance are incompatible; or if they had recollected that, according to their views, a community possessing the highest skill and exerting the utmost diligence, but scattered over a territory of unbounded extent and fertility, as they might be even unacquainted with the existence of such a thing as rent, must be totally without riches, must be poor from the mere prodigality of their resources.

In the following passage Mr. Ricardo seems to have fallen into an opposite error.

"Nothing is more common than to hear of the advantages which the land possesses over every other source of useful produce, on account of the surplus which it yields in the form of rent. Yet, when land is most abundant, when most productive, and most fertile, it yields no rent; and it is only when its powers decay, and less is yielded in return for labour, that a share of the original produce of the more fertile portions is set apart for rent. It is singular that this quality in the land, which should have been noticed as an imperfection, compared with the natural agents by which manufactures are assisted, should have been pointed out as constituting its peculiar pre-eminence. If air, water, the elasticity of steam, and the pressure of the atmosphere, were of various qualities, if they could have been appropriated, and each quality existed only in moderate abundance, they, as well as the land, would afford a rent, as the successive qualities were brought into use. With every worse quality employed, the value of the commodities in the manufacture of which they were used would rise, because equal quantities of labour would be less productive. Man would do more with the sweat of his brow, and nature would perform less; and the land would be no longer pre-eminent for its limited powers.

"If the surplus produce which the land affords in the form of rent be an advantage, it is desirable that every year the machinery newly constructed should be less efficient than the old, as that would undoubtedly give a greater exchangeable value to the goods manufactured, not only by that machinery, but by all other machinery in the Kingdom; and a rent would be paid to all those who possessed the most productive machinery.

"The labour of nature is paid not because she does much, but because she does little. In proportion as she becomes niggardly in her gifts, she exacts a greater price for her work. Where she is munificently beneficent she always works gratis." *Principles*, p. 63.

Mr. Ricardo seems to have forgotten that the quality which enables land to afford rent, namely, the power of producing the subsistence of more persons than are required for its cultivation, is an advantage without which rent could not have existed. As the population of any given district becomes more dense, the surplus produce of its soil, or, in other words, the amount of its produce which remains after provision has been made for the subsistence of those by whom it is cultivated, has a constant tendency to increase; either because the increase of agricultural skill and capital increases its positive fertility, or because a diminution of its relative fertility, a diminution of its produce relatively to the numbers of its cultivators, forces the poorer classes to be satisfied with a less amount of raw produce; or from both these causes combined. Of these two causes of rent, one is a benefit, the other an evil. That we have in this Country perhaps a million of acres capable of producing, with average labour, forty bushels of corn an acre, is a benefit; that we have not more than a million such acres is an evil. That the average amount of what an agricultural labourer produces much exceeds what is absolutely necessary for the subsistence of an agricultural family is a benefit. That the extent of our fertile land, and the amount of our capital, in proportion to our population, are not sufficient to enable him to consume, directly or indirectly, for his own advantage and that of his family, *all* that he produces, is an evil. To produce rent, both the benefit and the evil must coexist. The one occasions rent to be demanded; but it is the other which enables it to be paid.

Mr. Ricardo's attention seems to have been confined to the evil. But rent might be enormously increased without the increase of that evil, or even though that evil should be diminished. If the proprietor of a single estate could by a wish triple its produce, he would augment, in a much greater ratio, its rent. Would this increase be owing to the parsimony of nature? It may be said that it would be owing to the comparative unproductiveness of the rest of the Country. It must be admitted that, if we could suddenly triple the productive powers of all the land in this Country, the population remaining the same, the whole amount of rent would fall, and the condition of all classes, except of that comparatively small class which subsists on the rent of land, would be much improved. But if our population were also tripled, rents would be prodigiously increased, the situation of the landlords would be improved, and that of no other class deteriorated. In fact, the condition of all other classes would be improved, as the increased division of labour and ease of communication occasioned by a greater density of population would cheapen and improve our manufactures. If the population, instead of being tripled, were only doubled, the situation of the Country would be still better. The rise in rent, though not equal to what it would have been if the population had been tripled, would still be very great, and both raw produce and

---

consommer au gré de ses désirs, sans s'appauvrir, sans altérer le principe qui les reproduit sans cesse.

Le meilleur état possible est évidemment celui auquel est attachée la plus grande sûreté; il consiste donc dans la plus grande masse possible de valeurs disponibles; car ce sont les seules dont nous puissions toujours jouir, et sur lesquelles la sûreté puisse s'établir.

Je voudrois bien que mes lecteurs donnassent à cette vérité toute l'attention qu'elle mérite, je voudrois bien qu'ils saisissent que la richesse ne consiste que dans les valeurs disponibles, *qu'on peut consommer sans aucun inconvénient; par consequent, qu'il n'y a que le produit net des cultures qui soit richesse, parcequ'il est dans la masse des reproductions, la seule partie dont nous puissions disposer pour nos jouissances; le surplus de cette masse n'est pas disponible pour nous, il appartient à la culture, c'est elle qui tous les ans doit le consommer; nous ne pouvons le lui dérober, que nous n'en soyons punis par l'extinction de nos richesses.—L'Ordre Naturel, &c.*, p. 379—381.

Distribution. Proportions of rent, profit, and wages. Rent.

manufactures would be more abundant than they were previously. Now this is, in fact, what *has* occurred in England during the last hundred and thirty years. Since the beginning of the XVIIIth Century the population of England has about doubled. The produce of the land has certainly tripled, probably quadrupled. Rent has risen in a still greater proportion; but that rise has been accompanied by a rise of wages, estimated in every commodity consumed by the labourers, excepting a few, such as spirituous and fermented liquors, which have been made the subject of special taxation. With the same labour the labourer can obtain more corn, and perhaps five times as much of the most useful manufactures. Can it be fairly said that rents have risen because nature has done little? that the price paid for her assistance has been increased because she has become more niggardly in her gifts? It is true that, if the productiveness of the land, instead of being tripled, had been centupled, rents might not have risen; but it is equally true that they would not have risen if, instead of being tripled, it had remained stationary. The condition essential to the payment of the labour of nature is not, as Mr. Ricardo states it, that her assistance shall be little, but that it shall not be infinite.

As rent arises from the agency not of man, but of nature, its amount does not depend on the will or the exertions of its recipient. The owner of the land, or of the natural agent, whatever it be, for the use of which persons are willing to pay rent, receives the sum which their mutual competition forces them to give. As it is all pure gain, he accepts the largest sum that is offered, however trifling its amount. Nor, on the other hand, does the amount of rent depend on the will or the exertions of those who pay it. Whatever be the value of the services of an appropriated natural agent, that value must be paid by the person who wishes to use them, as both parties to the bargain are aware, that if it is not hired by one applicant it will be by another. The amount, therefore, is subject to no general rule; it has neither a minimum nor a maximum. It depends on the degree in which nature has endowed certain instruments with peculiar productive powers, and the number of those instruments compared with the number and wealth of the persons able and willing to hire them. There is, probably, now land near New York selling for £1000 an acre, which a century ago could have been obtained for a dollar.

Proportionate Amounts of Profit and Wages.

Proportions of profit and wages.

Profits and wages differ in almost all respects from rent. They are each subject to a minimum and a maximum. They are subject to a minimum, because each of them is the result of a sacrifice. It may be difficult to say what is the minimum with respect to profit, but it is clear that every capitalist, as a motive to abstain from the immediate and unproductive enjoyment of his capital, must require some remuneration exceeding the lowest that is conceivable. The minimum at which wages can be permanently fixed is of course the sum necessary to enable the existing labouring population to subsist. On the other hand, as the rate of wages depends in a great measure on the number of labourers, and the rate of profit on the amount of capital, both high wages and high profits have a tendency to produce their own diminution. High wages, by stimulating an increase of population, and therefore an increase of the number of labourers, and high profits, by occasioning an increase of capital. It will be seen in a future portion of this Treatise that, if the amount of capital employed in the payment of wages increases, the number of labourers remaining the same, profits will fall; and that if the number of labourers increases, the amount of capital and the productiveness of labour remaining the same, wages will fall; and that, if they both increase in equal proportions, both will have a tendency to fall, in consequence of the larger proportion which they will each bear to the power of the natural agents whose services they each require. And although it may not be easy to fix the maximum of either wages or profits, yet it may be laid down generally, that in no Country have profits continued for any considerable period at the average rate of fifty per cent. per annum, or wages at such a rate as to afford the labourer ten times the amount necessary for the subsistence of a family.

Adam Smith has laid down, that "the whole of the advantages and disadvantages of the different employments of labour and capital must, in the same neighbourhood, be either perfectly equal or continually tending to equality. If in the same neighbourhood there was any employment evidently either more or less advantageous than the rest, so many people would crowd into it in the one case, and so many would desert it in the other, that its advantages would soon return to the level of other employments. This at least would be the case in a society where things were left to take their natural course, where there was perfect liberty, and every man was perfectly free both to choose what occupation he thought proper, and to change it as often as he thought proper. Every man's interest would prompt him to seek the advantageous and to shun the disadvantageous employment." *Wealth of Nations*, book i. ch. x.

The truth of these remarks of Adam Smith is obvious. It is obvious also that, in the absence of disturbing causes, the desire of obtaining a more advantageous field for the employment of his mental and bodily faculties, which leads a man to move from one part of the same neighbourhood to another, would lead him from village to village and from Country to Country. For commercial purposes, the whole civilized world is one extended neighbourhood; and the same causes which tend to equalize profits in Liverpool and London tend to equalize them in London and Calcutta. But when we look into the details, we are struck by the difference in the remuneration of persons apparently undergoing equal toils, and exercising equal abstinence. We find a general exempt from more than half the hardships of a private, and receiving more than a hundred times his pay. We find barristers making £10,000 or £15,000 a year, while a copying clerk is paid for labour as assiduous and more irksome by only £100. We find the purchaser of an Exchequer-bill willing to pay a large premium for the privilege of advancing capital at a profit of three per cent. per annum, while a shopkeeper thinks himself ill paid by less than twenty per cent. We find a London banker satisfied with a profit of seven per cent., while his partner in Calcutta requires fifteen.

These differences are partly real and partly apparent. So far as they are real, they are occasioned partly by the influence of the different instruments of production, or, in other words, the different sources of revenue, on one another; the influence, for instance, of the rate of profits on the amount of wages, and of the amount of wages on the rate of profits; partly by the greater or less severity of the sacrifices which the labourer and the capitalist must make in addition to the undergoing mere toil or abstinence; and partly by the difficulty with which capital and labour are transferred from one employment to another. A difficulty caused partly by physical obstacles and partly by human habits and institutions. The influence of these causes on the average rates of wages and of profits in the same Country, in different employments of labour and capital, we shall consider hereafter; and having assumed for the purposes of the following discussion that a certain average rate of wages and a certain average rate of profit exists, we shall now endeavour to explain the causes by which these average rates are determined, or, in other words, to explain *the circumstances which decide what, at a given time and in a given place, shall be the average rate of wages and the average rate of profit.* We have already stated as one of the principal sources of difficulty in Political Economy the mutual dependence of its different propositions. A dependence which, as it respects the theory of wages and profits, is so great that it is impossible to give a complete view of the causes which affect the one without adverting to all those which affect the other. We shall endeavour to keep them as distinct as we can, and we shall begin by wages, as that subject is capable of being separately considered to the greatest extent.

Rate of wages.

Average Rate of Wages.

Meanings of the adjectives *high* and *low*, as applied to wages.

We have already defined wages to be the remuneration received by the labourer in recompense for having exerted his faculties of mind and body. They are said to be *high* or *low*, in proportion to the extent of that remuneration. That extent has been estimated by three different measures; and the words high and low wages have, consequently, been used in three different senses.

First. Wages have been termed high or low, according to the amount of *money* earned by the labourer within a given period, without any reference to the commodities which that money would purchase; as when we say that wages have *risen* in England since the reign of Henry VII., because the labourer now receives 1*s.* 6*d.* or 2*s.* a day, and then received only 4½*d.*

Secondly. They have been termed high or low, according to the *quantity and quality of the commodities* obtained by the labourer, without any reference to his receipts in money; as when we say that wages have *fallen* in England since the reign of Henry VII., because the labourer then earned two pecks of wheat a day, and now earns only one.

Thirdly. They have been termed high or low, according to the share or proportion which the labourer receives of the produce of his own labour, without any reference to the total amount of that produce.

The first nomenclature, that which measures wages simply by their amount in money, is the popular one. The second, that which considers wages simply with reference to the quantity and quality of the commodities received by the labourer, or, to speak more correctly, purchasable with his money wages, was that generally adopted by Adam Smith. The third, that which considers wages as high or low, simply with reference to the labourer's share or proportion of what he produces, was introduced by Mr. Ricardo, and has been continued by many of his followers.

Rate of wages. Meanings of the words *high* and *low*.

This last use of the words high and low wages has always appeared to us one of the most unfortunate of Mr. Ricardo's many innovations in the language of Political Economy. In the first place, it has a tendency to withdraw our attention, even when we are considering the subject of wages, from the facts which most influence the labourer's condition. To ascertain whether his wages are high or low, we are desired to inquire, not whether he is ill or well paid,—not whether he is well or ill fed, or clothed, or lodged, or warmed, but simply what proportion of what he produces comes to his share. During the last four or five years many a hand-weaver has received only 8*s.* 3*d.* for producing, by a fortnight's exertion, a web that the capitalist has sold for 8*s.* 4*d.* A coal-merchant often pays his men £2 a week, and charges his employers for their services £2 10*s.* But, according to Mr. Ricardo's nomenclature, the wages of the weaver, at 4*s.* 1½*d.* a week, are much higher than those of the coalheaver at £2, since the weaver receives 99 per cent. of the value of his labour, while the coalheaver has only 80 per cent.

And, even if the nomenclature in question were free from this objection, even if the point on which it endeavours to fix the attention were the most important, instead of being the least important, incident to wages, it still would be inconvenient from its tendency to render the writer who employs it both inconsistent and obscure. It is almost impossible to affix to terms of familiar use a perfectly new meaning, and not from time to time to slide into the old one. When Mr. Ricardo says that "nothing can affect profits but a rise of wages," p. 118; that "whatever raises the wages of labour lowers the profits of stock," p. 231; that "high wages invariably affect the employers of labour by depriving them of a portion of their real profits," p. 129; that "as the wages of labour fall the profits of stock rise," p. 499; he means by high wages, not a large *amount*, but a large *proportion*. But when he speaks of the "encouragement which high wages give to the increase of population," p. 88—361, he means by high wages a large *amount*. And many of his followers and opponents have supposed the words high and low to be used by him as indicative of quantity, not proportion. The consequence has been that, since the publication of his great Work, an opinion has prevailed that high wages and high profits are incompatible, and that whatever is taken from the one is added to the other. The slightest attempt to try this theory by an actual example will show its absurdity. The usual supposition is, that the capitalist, at an average, advances the wages of his labourers for one year, and receives, after deducting rent, one-tenth of the value of what they produce. We are inclined to think that in England the average rate of profit is rather greater, and the average period of advance rather less. After making many inquiries on these subjects in Manchester, we found the general opinion to be, that the manufacturing capitalist turns his capital, at an average, twice in the year, and receives on each operation a profit of 5 per cent.; and that the shopkeeper, at an average, turns his capital four times in a year, and receives on each operation a profit of about 3½ per cent. On these data the labourer's share would, of course, be much greater than according to the ordinary estimate. We will suppose, however, that estimate to be correct, and that, after rent has been deducted, the labourer receives, on an average, nine-tenths of the value of what he produces. Under these circumstances a rise in the amount of wages amounting to one-tenth, or from 10*s.* to 11*s.* a week, if that rise is to be deducted from the capitalist's share, would utterly destroy all profit whatever. A rise of one-fifth, or from 10*s.* to 12*s.* a week, would occasion to the capitalist a loss equal to the whole amount of his former profit. A fall in wages of one-tenth would double profits; a fall of one-fifth would treble them. Now we know that general variations in the amount of wages to the amount of one-tenth or one-fifth, or to a greater extent, are not of unfrequent occurrence. Yet who ever heard of their producing such an effect on profits?

And yet this doctrine has received the sanction both of theoretic and practical men. Mr. Francis Place is asked by the Committee on Artisans and Machinery (First Report, p. 46,*) "Do not the masters in consequence of a rise of wages raise their prices?"—"No," he answers; "I believe there is no principle of Political Economy better established than this of wages; increase of wages must come from profits."

Did Mr. Place ever apply this doctrine when his men asked for higher wages on a general mourning? Even the Committee appear to have taken this view of the question. The subject is so important, that we will venture to extract the following passage from the Report made in the following Session:—

"Those eminent persons who, during the last fifty years, have reduced the rules that govern the operations of trade and industry to a Science, undertake to show, by arguments and facts, that the effect of low wages is not a low price of the commodity to which they are applied, but the raising of the average rate of profits in the Country in which they exist. The explanation of this proposition occupies a large portion of the justly-celebrated work of the late Mr. Ricardo, on the Principles of Political Economy; and is also ably set forth in the following evidence of Mr. M'Culloch, to which your Committee particularly desire to draw the attention of the House:

"'Have you turned your attention to the effect of fluctuations in the rate of wages on the price of commodities?'—'I have.'

"'Do you consider that when wages rise the price of commodities will proportionally increase?'—'I do not think that a real rise of wages has any effect whatever, or but a very imperceptible one, on the price of commodities.'

"'Then, supposing wages to be really lower in France than in this Country, do you think that that circumstance would give the French any advantage over us in the foreign market?'—'No, I do not; I do not think it would give them any advantage whatever. I think it would occasion a different distribution of the produce of industry in France from what would obtain in England, but that would be all. In France the labourers would get a less proportion of the produce of industry, and the capitalists a larger proportion.'

"'Could not the French manufacturer, if he gets his labour for less than the English manufacturer, afford to sell his goods for less?'—'As the value of goods is made up wholly of labour and profit, the whole and only effect of a French manufacturer getting his labour for less than an English manufacturer is to enable him to make more profit than the English manufacturer can make, but not to lower the price of his goods. The low rate of wages in France goes to establish a high rate of profits in all branches of industry in France.'

"'What conclusion do you come to in making a comparison between wages in England and wages in France?'—'I come to this conclusion, that, if it be true that wages are really higher in England than in France, the only effect of that would be to lower the profits of capital in England below their level in France, but that will have no effect whatever on the price of the commodities produced in either Country.'

"'When you say that wages do not affect prices, what is it that does affect prices?'—'An increase or diminution of the quantity of labour necessary to the production of the commodity.'

"'Supposing that there was a free export of machinery, so that France could get that machinery, do you think that under those circumstances we should retain those advantages which we possess at the present moment?'—'Yes, we should; for the export of the machinery would not lower our wages, or increase the wages in France, so that we should preserve that advantage to the full extent that we have it at this moment.'

"'Will you explain to the Committee why you are of opinion that the French manufacturer would not undersell the English, seeing that his profits are larger than the English manufacturer?'—'Because, if he were to offer to undersell the English, he can only do it by consenting to accept a less rate of profit on his capital than the other French capitalists are making on theirs, and I cannot suppose a man of common sense would act upon such a principle.'

"'Are the Committee to understand, that although a French manufacturer pays half the wages to his men in France which our manufacturers do in England, yet that his wages being on a par, or a level, in general, with the other wages in France, will render his profits on a par with them, and consequently he would not undersell the English merchant by lowering his profits below the average rate of profits in France?'—'Precisely so. I believe, in point of fact, there is no such difference; but he could not undersell the English manufacturer unless he took lower profits than all other producers in France were making. I might illustrate this by what takes place every day in England, where you never find the proprietor of rich land, in order to get rid of his produce, offering it in Mark-lane at a lower rate than that which is got by a farmer or proprietor of the very worst land in the Kingdom.'

"'Would it not produce a larger sale if the French manufacturer were to sell at a less price?'—'Supposing that to be so, the greater the sale the greater would be the loss of profit.'"*

We have extracted this passage as indicating the views of the Committee, not those of Mr. M'Culloch. Mr. M'Culloch, as will appear on turning to his evidence, meant by wages *really high* and *really low*, not a larger or a smaller amount, but a larger or a smaller proportion. But the Committee appear to have understood him to mean a larger or a smaller amount.

Mr. Bradbury had previously stated the common day wages in France to be about half the wages paid in England.

He was asked, "In what way do you consider that lower wages in France give the French manufacturers an advantage over English manufacturers?"—"I conceive that if they pay 3*d.* a pound for spinning to the

---

* Session of 1824.

* Report from Select Committee on Export of Tools and Machinery. Session of 1825, p. 13, 14.

Distribution. Meanings of the words *high* and *low*

operative spinner, and we pay 6*d*., that would give them an advantage of 3*d*. a pound in the cost."

"You mean to say that the French would be able to sell the article they make, in consequence of paying lower wages, cheaper than the English could sell it?"—"They could afford it 3*d*. a pound cheaper."

"You mean to say that, according to the rate of wages paid, the price of the article for which they are paid is high or low?"—"It may be afforded higher or lower, I should imagine, as the cost be more or less."

"Therefore the whole reason and ground on which you think that low wages give them an advantage is, that low wages contribute to enable them to sell the article cheaper than if they paid higher wages?"—"Yes, labour constituting a material feature in the cost"

"You conceive that increased cost would be a loss to the party, if the price was not increased in proportion?"—"I should imagine so."

"*Might not the profits of the proprietor be lessened?*"—"*They might be lessened, which is in effect a loss.*"

"*Might not that enable him to bear the loss which the difference of wages produces?*" *—"*If he chose to make that sacrifice.*"

"Might not the profits be lessened until there were no profits at all!"†—"Very easily, I should think."—(Fifth Report of the Select Committee on Artisans and Machinery, p. 547, 549, 550.)

It was with reference to this evidence that Mr. M'Culloch was examined. His examination commences thus:

"Have you read the evidence which has been given before this Committee?"—"I have read portions of it only."

"Have you read the evidence given by Mr. Bradbury?"—"A part of it."

"That part in which he conceives that foreigners have an advantage over the English manufacturers in consequence of wages being lower in France?"—"Yes, I have read that."

And then follows the question:

"Have you turned your attention to the effect of fluctuations in the rate of wages on the price of commodities?"

Now if the Committee understood Mr. M'Culloch to mean, by high or low wages, not a great or small amount, but a great or small proportion, his evidence and that of Mr. Bradbury had nothing in common.

The whole of the confusion has been occasioned by the verbal ambiguity which we have pointed out, and would not have arisen if Mr. Ricardo had used any other adjectives than *high* and *low* to express a larger or smaller proportion.

The two other meanings of the words high and low wages, that which refers to the money, and that which refers to the commodities, received by the labourer, are both equally convenient, if we consider the rate of wages *at the same time and place*; for then they both mean the same thing. At the same time and place the labourer who receives the highest wages necessarily obtains the most commodities. But when we refer to different places, or different times, the words high or low wages direct the attention to very different subjects, as we understand them to mean more or less in money, or more or less in commodities. The differences which have taken place in the amount of money wages at different times inform us of scarcely any thing but the abundance or scarcity of the precious metals at those times: facts which are seldom of much importance. The differences in the amount of money wages in different places at the same time are of much more importance, since they indicate the different values of the labour of different Countries in the general market of the world. But even these differences afford no premises from which the positive condition of the labouring classes, in any Country, can be inferred, and but imperfect grounds for estimating their relative condition. The only data which enable us to ascertain the actual situation of the labourers at any given time and place, or their comparative situation at different times and places, are the quantity and quality of the commodities which form their wages, if paid in kind, or are purchasable with their wages, if paid in money. And as the actual or comparative situation of the labourer is the principal object of the following inquiry, we shall use the word wages to express, not the money, but the commodities, which the labourer receives; and we shall consider wages to rise as the quantity or quality of those commodities is increased or improved, and to fall as that quantity or quality is diminished or deteriorated.

Distribution. Rate of wages. Meanings of the words *high* and *low*.

It is obvious, too, that the labourer's situation does not depend on the amount which he receives at any one time, but on his average receipts during a given period—during a week, a month, or a year; and that the longer the period taken, the more accurate will be the estimate. Weekly wages have, of course, more tendency to equality than daily ones, and annual than monthly; and, if we could ascertain the amount earned by a man during five, or ten, or twenty years, we should know his situation better than if we confined our attention to a single year. There is, however, so much difficulty in ascertaining the amount of wages during very long periods, that a single year will probably be the best that we can take. It comprehends what, in most climates, are very different, summer and winter wages; it comprehends also the period during which the most important vegetable productions come to maturity in temperate climates, and on that account has generally been adopted by Political Economists as the average period for which capital is supposed to be advanced.

We should observe that we include, as part of the wages of the married labourer, those of his wife and unemancipated children. To omit them would lead to inaccurate estimates of the comparative situation of the labourers in different Countries, or in different occupations. In those employments which are carried on under shelter, and with the assistance of that machinery which affords power, and requires human aid only for its direction, the industry of a woman, or a child, approaches in efficiency that of a full-grown man. A girl of fourteen can manage a power-loom nearly as

---

* In other words, "Might not the loss enable him to bear the loss?"

† This question appears to have come from a different interrogator. In justice to the clear and intelligent evidence of Mr. Bradbury, we should observe that he was far from falling into the common error, that a generally high rate of wages can be unfavourable to a Country. He set out by supposing that, with the assistance of English machinery and English superintendents, the labour of the French spinners might be as productive as that of the English spinners. Under such circumstances, if their wages could remain at one-half of English wages, he believed that the French manufacturer could undersell the English manufacturer. Of the accuracy of this opinion under the possible, though highly improbable hypothesis in question, we entertain no doubt, though, from the tenour of the questions, it appears not to have met with the approbation of the Committee.

Distribution. Rate of wages. Meanings of the words *high* and *low*.

well as her father; but where strength, or exposure to the seasons, is required, little can be done by the wife, or the girls, or even by the boys, until they approach the age at which they usually quit their father's house. The earnings of the wife and children of many a Manchester weaver or spinner exceed, or equal, those of himself. Those of the wife and children of an agricultural labourer, or of a carpenter, or a coalheaver, are generally unimportant—while the husbands, in each case, receives 15*s*. a week, the weekly income of the one family may be 40*s*., and that of the other only 17*s*. or 18*s*.

It must be admitted, however, that the workman does not retain the whole of this apparent pecuniary advantage. The wife is taken from her household labours, and a part of the increased wages is employed in purchasing what might, otherwise, be produced at home. The evils to the children are still greater. The infants suffer from the want of maternal attention, and those who are older from fatigue and confinement, from the want of childish relaxation and amusement, and, what is far more important, from the deficiency of religious, moral, and intellectual education. The establishment of infant and Sunday schools, and laws regulating the number of hours during which children may labour, are palliatives of these evils, but they must exist, to a certain degree, whenever the labour of the wife and children is the subject of sale; and, though not, all of them, perhaps, strictly within the province of Political Economy, must never be omitted in any estimate of the causes affecting the welfare of the labouring classes.

The last preliminary point to which we have to call the reader's attention is, the difference between the *amount of wages* and the *price of labour*, or, in other words, between the earnings of a labourer during a given time and the price paid for the performance of a given quantity of work.

If men were the only labourers, and if every man worked equally hard, and for the same number of hours, during the year, these two expressions would be synonymous. If each man, for instance, worked three hundred days during each year, and ten hours during each day, one three-thousandth part of each man's yearly wages would be the price of an hour's labour. But neither of these propositions is true. The yearly wages of a family often include, as we have seen, the results of the labour of the wife and children. And few things are less uniform than the number of working days during the year, or of working hours during the day, or the degree of exertion undergone during those hours.

The established annual holidays in Protestant Countries are between fifty and sixty. In many Catholic Countries they exceed one hundred. Among the Hindoos they are said to occupy nearly half the year. But these holidays are confined to a certain portion of the population; the labour of a sailor, or a soldier, or a menial servant, admits of scarcely any distinction of days.

Again, in Northern and Southern latitudes, the hours of out-door labour are limited by the duration of light; and in all climates by the weather. When the labourer works under shelter, the daily hours of labour may be uniform throughout the year. And, independently of natural causes, the daily hours of labour vary in different Countries, and in different employments in the same Country. The daily hours of labour are, perhaps, longer in France than in England, and certainly are longer in England than in Hindostan. In Manchester the manufacturer generally works twelve hours a day; in Birmingham, ten: a London shopman is seldom employed more than eight or nine.

Distribution. Rate of wages. Difference between the amount of wages and the price of labour.

There is still more discrepancy between the exertions made by different labourers in a given period. They are often, indeed, unsusceptible of comparison. There is no common measure of the toils undergone by a miner and a tailor, or of those of a shopman and an ironfounder. And labour which is the same in kind may vary indefinitely both in intensity and in productiveness. Many of the witnesses examined by the Committee on Artisans and Machinery (Session of 1824) were English manufacturers, who had worked in France. They agree as to the comparative indolence and inefficiency of the French labourer, even during his hours of employment. One of the witnesses, Adam Young, had been two years in one of the best manufactories in Alsace. He is asked, "Did you find the spinners there as industrious as the spinners in England?" and replies, "No; a spinner in England will do twice as much as a Frenchman. They get up at four in the morning, and work till ten at night; but our spinners will do as much in six hours as they will in ten."

"Had you any Frenchmen employed under you?"—"Yes; eight, at two francs a day."

"What had you a day?"—"Twelve francs"

"Supposing you had had eight English carders under you how much more work could you have done?"—"With one Englishman I could have done more than I did with those eight Frenchmen. It cannot be called work they do: it is only looking at it, and wishing it done."

"Do the French make their yarn at a greater expense?"—"Yes; though they have their hands for much less wages than in England."—pp. 580, 582.

The following evidence of Edwin Rose, given on the Factory Inquiry of 1833, relates to a rather later period, and is valuable from the extensive experience of the witness.

"Are wages lower in France, as far as you have seen, than in England?"—"If I have a shop of men in England for any thing, then I have to see how much I have to pay them for the work they turn out of any kind; but if I have the same shop in France, then I must have twice the number of hands to do the same amount of work. It is true I pay them less apiece there; but I have seen that you must have twice as large a building to contain the hands, twice as many clerks and book-keepers, and overlookers to look after them, and twice as many tools to do the same quantity of work as is done here in England; and the master there must have twice as much interest of money on all this; and their minds seem to me to get more bewildered with stress of work there than here. It seems to me that you have double the number of people there to do the same amount of work, whatever it be; but their wages are lower in money."

"But do you consider their wages higher in reality?"—"I really do; they are better paid in proportion to the work they turn out than what the English are."

"What do you think of French workmen, as workmen?"—"I don't think they have that perseverance that English have. I often have noticed them trying a thing, and then, if it don't answer at first, they seem terrified and shrug up their shoulders, and throw it aside; but an English workman keeps trying and trying, and won't give up near so soon as the Frenchman. A house-

Distribution. Rate of wages. Difference between the amount of wages and the price of labour.

joiner or carpenter's wages are from thirty-five to forty sous a day. His work compared with English work is very rough, and but little of it in comparison. A stonemason's wages are from three francs to four francs. They are inferior to our masons in laying foundations. Then, as to time of work, I think two English masons in the same time do more work on an average than three of theirs."

"In short, do you know any single species of labour that stands a master cheaper in France than in England, quality and quantity of work being considered?"—"I don't know any, unless it be tailors and shoemakers' wages; and I am not sure about them. Clothes are dearer in France than in England; but shoes are cheaper, the duty being off leather." *First Report of the Factory Commission*, D. i. p. 121.

Even in the same Country, and in the same employments, similar inequalities are constantly observed. Every one is aware that much more exertion is undergone by the labourer by task-work than by the day-labourer; by the independent day-labourer than by the pauper; and even by the pauper than by the convict.

It is obvious that the rate of wages is less likely to be uniform than the price of labour, as the amount of wages will be affected, in the first place, by any variations in the price, and, in the second place, by any variations in the amount, of the labour exerted.

In England the average annual wages of labour are three times as high as they are in Ireland; but as the labourer in Ireland is said not to do more than one-third of what is done by the labourer in England, the price of labour may, in both Countries, be about equal. In England the labourer by task-work earns much more than the day-labourer; but, as it is certainly as profitable to employ him, the price of his labour cannot be higher. It may be supposed, indeed, that the price of labour is every where, and at all times, the same; and, if there were no disturbing causes,—if all persons knew perfectly well their own interest, and strictly followed it, and there were no difficulties in moving capital and labour from place to place, and from employment to employment,—the price of labour, at the same time, would be every where the same. But these difficulties occasion the price of labour to vary materially, even at the same time and place; and variations both in the amount of wages and in the price of labour, at different times and in different places, are occasioned not only by these causes, but by others which will be considered in a subsequent part of this Treatise.

These variations affect very differently the labourer and his employer. The employer is interested in keeping down the price of labour; but while that price remains the same, while at a given expense he gets a given amount of work done, his situation remains unaltered. If a farmer can get a field trenched for £12, it is indifferent to him whether he pays the whole of that sum to three capital workmen, or to four ordinary ones. The three would receive higher wages than the four, but, as they would do proportionably more work, their labour would come just as cheap. If the three could be hired at £3 10*s*. apiece, while the four required £3 apiece, though the wages of the three would be higher, the price of the work done by them would be lower.

It is true that the causes which raise the amount of the labourer's wages often raise the rate of the capitalist's profits. If, by increased industry, one man performs the work of two, both the amount of wages and the rate of profits will generally be raised. But the rate of profit will be raised, not by the rise of wages, but in consequence of the additional supply of labour having diminished its price, or having diminished the period for which it had previously been necessary to advance that price, or having rendered, as in the instances mentioned by Edwin Rose, the labour previously employed more productive.

The labourer, on the other hand, is principally interested in the amount of wages. The amount of his wages being fixed, it is certainly his interest that the price of his labour should be high, for on that depends the degree of exertion imposed on him. But, if the amount of his wages be low, he must be comparatively poor—if that amount be high he must be comparatively rich—whatever be his remuneration for each specific act of exertion. In the one case he will have leisure and want; in the other toil and abundance. We are far from thinking that the evils of severe and incessant labour, or the benefits of a certain degree of leisure, ought to be left out in any estimate of happiness. But, as we observed in the beginning of this Treatise, it is not with happiness, but with wealth, that we are concerned as Political Economists; we profess to state facts for the information and instruction of the student, not to lay down rules to guide the conduct of the legislator. In explaining the general laws according to which wealth is produced and distributed we do not assume that all the means by which it can be augmented ought to be encouraged, or even to be permitted. We do not assume even that wealth is a benefit. In fact, however, wealth and happiness are very seldom opposed. Nature, when she imposed on man the necessity of labour, tempered his repugnance to it by making long-continued inactivity painful, and by strongly associating with exertion the idea of its reward. The poor and half-employed Irish labourer, or the still poorer and less industrious savage, is as inferior in happiness as he is in income to the hard-worked English artisan. The Englishman's industry may sometimes be excessive; his desire to better his condition may sometimes drive him on toils productive of disease ill recompensed by the increase of his wages; but that such is not generally the case may be proved by comparing the present duration of life in England with its former duration, or with its duration in other Countries. It is generally admitted that, during the last fifty years, a marked increase has taken place in the industry of our population, and that they are now the hardest-working labourers in the world. But during the whole of that period the average duration of their lives has been constantly increasing, and appears still to increase; and, notwithstanding the apparent unhealthiness of many of their occupations, notwithstanding the atmosphere of smoke and steam, and, what appears to be still more injurious, of dust, in which many of them labour for sixty-nine hours a week, they enjoy, as a community, longer life than the lightly-toiled inhabitants of the most favoured soils and climates.

The average annual mortality in England and Wales is computed by Mr. Rickman at one in forty-nine. In the extensive inquiry instituted by the Poor-Law Commissioners in 1834 into the state of the labouring classes in America and the Continent of Europe, the only Countries in which the mortality appeared to be so small as in England were Norway, in which it appeared to be one in fifty-four, and the Basses Pyrenees, in which it appeared to be one in fifty. In all the other Countries

Distribution. Rate of wages. Difference between the amount of wages and the price of labour.

which gave returns it exceeded the English proportion sometimes by doubling it, and in the majority of instances by more than one-fourth.*

Having marked the distinction which really exists between the price of labour and the amount of wages, we shall for the future consider every labouring family as consisting of the same number of persons, and exerting the same degree of industry. On that supposition, the distinction between the price of labour and the amount of wages will be at an end; or rather, the only distinction will be, that the former expression designates the remuneration for each specific exertion; the latter, the aggregate of all those separate remunerations, as summed up at the end of each year. And the question to be answered will be, what are the causes which decide what in any given Country, and at any given period, shall be the quantity and quality of the commodities obtained by a labouring family during a year?

Proximate Cause deciding the Rate of Wages.

The proximate cause appears to be clear. The quantity and quality of the commodities obtained by each labouring family during a year must depend on the quantity and quality of the commodities directly or indirectly appropriated during the year to the use of the labouring population, compared with the number of labouring families, (including under that term all those who depend on their own labour for subsistence;) or, to speak more concisely, on the extent of the fund for the maintenance of labourers, compared with the number of labourers to be maintained.

This proposition is so nearly self-evident, that if Political Economy were a new Science we should assume it without further remark. But we must warn our readers that this proposition is inconsistent with opinions which are entitled to consideration, some from the number, and others from the authority, of those who maintain them.

Erroneous Opinions.

First. It is inconsistent with *the doctrine that the rate of wages depends solely on the proportion which the number of labourers bears to the amount of Capital in a Country.* The word capital has been used in so many senses that it is difficult to state this doctrine precisely; but we know of no definition of that term which will not include many things that are not used by the labouring classes; and, if our proposition be correct, no increase or diminution of *these* things can *directly* affect wages. If half the plate glass in the Country were to be destroyed to-morrow the capital of the Country would be diminished; but the only sufferers would be those who possess or wish to possess plate glass; among whom the labouring classes are not included. But if half the existing stock of coarse tobacco were destroyed, the immediate consequence would be a fall of wages; not as estimated in money, but as estimated in the commodities consumed by the labourer. Though receiving the same money wages, the labourer would have less tobacco, or, if he chose to continue undiminished his consumption of tobacco, then less of other things, than he had before. So if a foreign merchant were to come to settle in this Country, and bring with him a cargo of raw and manufactured silk, lace, and diamonds, that cargo would increase the capital of the Country; silk, lace, and diamonds would become more abundant, and the enjoyments of those who use them would be increased: the enjoyments of the labourers, supposing them not to be consumers of silk, lace, or diamonds, would not be directly increased: indirectly and consequentially, they might be increased. The silk might be re-exported in a manufactured state, and commodities for the use of labourers imported in return; and then, and not till then, wages would rise; but that rise would be occasioned, not by the first addition to the capital of the Country, which was made in the form of silk, but by the substituted addition made in the form of commodities used by the labourer.

Secondly. It is inconsistent with *the doctrine, that wages depend on the proportion borne by the number of labourers to the whole revenue of the society of which they are members.* In the example last suggested, of the introduction of a new supply of lace or diamonds, the *revenues* of those who use lace or diamonds would be increased; but as wages are not spent on those articles, *they* would remain unaltered. It is possible, indeed, to state cases in which the revenue of a large portion of a community might be increased, and yet the wages of the labourers might fall without an increase of their numbers. We will suppose the principal trade of Ireland to be the raising produce for the English market; and that for every two hundred acres ten families were employed in raising, on half the land, their own subsistence, and on the remainder corn and other exportable crops requiring equal labour. Under such circumstances, if a demand should arise in the English market for cattle, butchers'-meat, and wool, instead of corn, it would be the interest of the Irish landlords and farmers to convert their estates from arable into pasture. Instead of ten families for every two hundred acres, two might be sufficient: one to raise the subsistence of the two, and the other to tend the cattle and sheep. The revenue of the landlords and the farmers would be increased: and, if they employed the whole of that increase in the purchase of Irish labour, all parties would be benefited. But if they devoted the greater part of it to the purchase of English manufactures, the services of a large portion of the Irish labourers would cease to be required; a large portion of the land formerly employed in producing commodities for their use would be devoted to the production of commodities for the use of England; and the fund for the maintenance of Irish labour would fall, notwithstanding the increase of the revenue of the landlords and farmers.

Absenteeism.

Thirdly. It is inconsistent with *the prevalent opinion, that the non-residence of landlords, funded proprietors, mortgagees, and other unproductive consumers, can be detrimental to the labouring inhabitants of a Country which does not export raw produce.*

In a Country *which exports raw produce*, wages *may* be lowered by such non-residence. If an Irish landlord resides on his estate, he requires the services of certain persons, who must also be resident there, to minister to his daily wants. He must have servants, gardeners, and perhaps gamekeepers. If he build a house, he must employ resident masons and carpenters; part of his furniture he may import, but the greater part of it must be made in his neighbourhood; a portion of his land, or, what comes to the same thing, a portion of his rent, must be employed in producing food, clothing, and shelter for all these persons, and for those who produce that food, clothing, and shelter. If he were to remove to England, all these wants would be supplied by Englishmen. The land and capital which was formerly employed in providing the maintenance of Irish labourers would be employed in producing corn and cattle to be exported to England to provide the subsistence of English labourers. The whole quantity of commodities appropriated to the use of Irish labourers would be diminished, and that appropriated to the use of English labourers increased, and wages would, consequently, rise in England, and fall in Ireland.

---

* Senior, *Preface to Foreign Communications*, p. 238.

It is true that these effects would not be co-extensive with the landlord's income. While, in Ireland, he must have consumed many foreign commodities, he must have purchased tea, wine, and sugar, and other things which the climate and the manufactures of Ireland do not afford, and he must have paid for them by sending corn and cattle to England. It is true, also, that while in Ireland he probably employed a portion of his land and of his rents for other purposes, from which the labouring population received no benefit, as a deer park, or a pleasure garden, or in the maintenance of horses or hounds. On his removal, that portion of his land which was a park would be employed, partly in producing exportable commodities, and partly in producing subsistence for its cultivators; and that portion which fed horses for his use might be employed in feeding horses for exportation. The first of these alterations would do good; the second could do no harm. Nor must we forget that, through the cheapness of conveyance between England and Ireland, a portion, or perhaps all, of those whom he employed in Ireland might follow him to England, and, in that case, wages in neither Country would be affected. The fund for the maintenance of labourers in Ireland, and the number of labourers to be maintained, would both be equally diminished, and the fund for the maintenance of labourers in England, and the number of labourers to be maintained, would both be equally increased.

But after making all these deductions, and they are very great, from the supposed effect of the absenteeism of the Irish proprietors on the labouring classes in Ireland, we cannot agree with Mr. M'Culloch that it is immaterial. We cannot but join in the general opinion that their return, though it would not affect the prosperity of the British Empire, considered as a whole, would be immediately beneficial to Ireland, though perhaps too much importance is attached to it.

In Mr. M'Culloch's celebrated examination before the Committee on the state of Ireland, (4th Report, 814, Sess. 1825.) he was asked, "Supposing the largest export of Ireland were in live cattle, and that a considerable portion of rent had been remitted in that manner, does not such a mode of producing the means of paying rent contribute less to the improvement of the poor than any extensive employment of them in labour would produce?—He replies, "Unless the means of paying rent are changed when the landlord goes home, his residence can have no effect whatever."

"Would not," he is asked, "the population of the country be benefited by the expenditure among them of a certain portion of the rent which (if he had been absent) has (would have) been remitted (to England)?" "No," he replies, "I do not see how it could be benefited in the least. If you have a certain value laid out against Irish commodities in the one case, you will have a certain value laid out against them in the other. The cattle are either exported to England, or they stay at home. If they are exported, the landlord will obtain an equivalent for them in English commodities; if they are not, he will obtain an equivalent for them in Irish commodities; so that in both cases the landlord lives on the cattle, or on the value of the cattle: and whether he lives in Ireland or in England, there is obviously just the very same amount of commodities for the people of Ireland to subsist upon."

This reasoning assumes that the landlord, while resident in Ireland, himself personally devours all the cattle produced on his estates; for on no other supposition can there be the very same amount of commodities for the people of Ireland to subsist upon, whether their cattle are retained in Ireland or exported.

But when a Country does *not* export raw produce, the consequences of absenteeism are very different. Those who derive their incomes from such a Country cannot possibly spend them abroad until they have previously spent them at home.

When a Leicestershire landlord is resident on his estate, he employs a certain portion of his land, or, what is the same, of his rent, in maintaining the persons who provide for him those commodities and services, which must be produced on the spot where they are consumed. If he should remove to London, he would want the services of Londoners, and the produce of land and capital which previously maintained labourers resident in Leicester would be sent away to maintain labourers resident in London. The labourers would probably follow, and wages in Leicestershire and London would *then* be unaltered; but until they did so, wages would rise in the one district and fall in the other. At the same time, as the rise and fall would compensate one another, as the fund for the maintenance of labour, and the number of labourers to be maintained, would each remain the same, the same amount of wages would be distributed among the same number of persons, though not precisely in the same proportion as before.

If he were now to remove to Paris, a new distribution must take place. As the price of raw produce is lower in France than in England, and the difference in habits and language between the two Countries prevents the transfer of labourers from the one to the other, neither the labourers nor the produce of his estates could follow him. He must employ French labourers, and he must convert his share of the produce of his estate, or, what is the same thing, his rent, into some exportable form in order to receive it abroad. It may be supposed that he would receive his rent in money. Even if he were to do so, the English labourers would not be injured, for as they do not eat or drink money, provided the same amount of commodities remained for their use, they would be unaffected by the export of money. But it is impossible that he could receive his rent in money unless he chose to suffer a gratuitous loss. The rate of exchange between London and Paris is generally rather in favour of London, and scarcely ever so deviates from par between any two Countries, as to cover the expense of transferring the precious metals from the one to the other, excepting between the Countries which do, and those which do not, possess mines. The remittances from England to France must be sent, therefore, in the form of manufactures, either directly to France, or to some Country with which France has commercial relations. And how would these manufactures be obtained? Of course in exchange for the landlord's rent. His share of the produce of his estates would now go to Birmingham or Sheffield, or Manchester or London, to maintain the labourers employed in producing manufactures, to be sent and sold abroad for his profit. An English absentee employs his income precisely as if he were to remain at home and consume nothing but hardware and cottons. Instead of the services of gardeners and servants, upholsterers and tailors, he purchases those of spinners, and weavers, and cutlers. In either case his income is employed in maintaining labourers, though the class of labourers is different; and in either case, the whole fund for the maintenance of labourers, and the number of labourers to be maintained, remaining unaltered, the wages of labour cannot be affected.

But, in fact, that fund would be rather increased in quantity and rather improved in quality. It would be increased, because land previously employed as a park, or in feeding dogs and horses, or hares and pheasants, would now be employed in producing food or clothing for men. It would be improved, because the increased production of manufactured commodities would occasion an increased division of labour, the use of more and better machinery, and the other improvements which we have ascertained to be its necessary accompaniments.

One disadvantage, and one only, it appears to us would be the result. The absentee in a great measure escapes domestic taxation. We say *in a great measure*, because he still remains liable, if a proprietor of houses or of land, to those taxes which fall upon rent: he pays, too, a part of the taxes on the materials of manufactures; and if it were our policy to tax income or exported commodities, he might be forced to pay to the public revenue even more than his former proportion. But, under our present system, which throws the bulk of taxation on commodities produced for internal consumption, he receives the greater part of his revenue without deduction, and, instead of contributing to the support of the British Government, contributes to support that of France or Italy. This inconvenience, perhaps, about balances the advantages which we have just mentioned, and leaves a community which exports only manufactures neither impoverished nor enriched by the residence abroad of its unproductive members.

We ought, perhaps, on this occasion again to remind our readers that it is to wealth and poverty that our attention, when writing on Political Economy, is confined. The *moral* effects of absenteeism must never be neglected by a writer who inquires into the causes which promote the *happiness* of nations, but are without the province of a Political Economist. Nor do we regret that they are so, for they form a subject on which it is far more difficult to obtain satisfactory results. In one respect, indeed, the moral question is the more simple, as it is not complicated by the consideration whether raw produce or manufactures are exported, or whether the non-resident landlord is abroad, or in some town within his own Country. If his presence is to be morally beneficial, it must be his presence on his own estate. To the inhabitants of that estate the place to which he absents himself is indifferent. Adam Smith believed his residence to be morally injurious. "The residence of a Court," he observes. (book ii. ch. iii.) "in general makes the inferior sort of people dissolute and poor. The inhabitants of a large village, after having made considerable progress in manufactures, have become idle in consequence of a great Lord having taken up his residence in their neighbourhood." And Mr. M'Culloch, whose fidelity and intelligence as an observer may be relied on, states, as the result of his own experience, that in Scotland the estates of absentees are almost always the best managed. Much, of course, depends on individual character; but we are inclined to believe that, in general, the presence of men of large fortune is morally detrimental, and that of men of moderate fortune morally beneficial, to their immediate neighbourhood. The habits of expense and indulgence which, in different gradations, prevail among all the members of a great establishment, are mischievous as examples, and perhaps still more so as sources of repining and discontent. The drawing-room and stable do harm to the neighbouring gentry, and the housekeeper's room and servants' hall to their interiors. But families of moderate income, including under that term incomes between £500 and £2000 a year, appear to be placed in the station most favourable to the acquisition of moral and intellectual excellence, and to its diffusion among their associates and dependents. We have no doubt that a well-regulated gentleman's family, removing the prejudices, soothing the quarrels, directing and stimulating the exertions, and awarding praise or blame to the conduct of the villagers round them, is among the most efficient means by which the character of a neighbourhood can be improved. It is the happiness of this Country that almost every parish has a resident fitted by fortune and education for these services; and bound, not merely by feelings of propriety, but as a matter of express and professional duty, to their performance. The dispersion throughout the Country of so many thousand clerical families, each acting in its own district as a small centre of civilization, is an advantage to which, perhaps, we have been too long accustomed to be able to appreciate its extent.

Still, however, we think that even the moral effects of absenteeism have been exaggerated. Those who declaim against the twelve thousand English families supposed to be resident abroad, seem to forget that not one-half, probably not one-quarter, of them, if they were to return, would dwell any where but in towns, where their influence would be wasted, or probably not even exerted. What does it signify to the Northumbrian or Devonshire peasant whether his landlord lives in London, or Cheltenham, or Rome? And even of those who would reside in the country, how many would exercise that influence beneficially? How many would be fox-hunters or game-preservers, or surround themselves with dependents whose example would more than compensate for the virtues of their masters? Nothing can be more rash than to predict that *good* would be the result of causes which are quite as capable of producing evil.

The economical effects have been still more generally misunderstood; and we have often been tempted to wonder that doctrines so clear as those which we have just been submitting to our readers should be admitted with reluctance even by those who feel the proofs to be unanswerable, and should be rejected at once by others, as involving a paradox too monstrous to be worth examination.

Much of this, probably, arises from a confusion of the economical with the moral part of the question. Many writers and readers of Political Economy forget that the clearest proof that absenteeism diminishes the virtue or the happiness of the remaining members of a community is no answer to arguments which aim only at proving that it does not diminish their wealth.

Another and perhaps the chief source of error is the circumstance that, when the landlord is present, the gain is concentrated, and the loss diffused, when he is absent the gain is diffused, and the loss concentrated. When he quits his estate, we can put our finger on the village tradesman and labourer who lose his custom and employment. We cannot trace the increase of custom and employment that is consequently scattered among millions of manufacturers. When he returns, we see that the expenditure of £2000 or £3000 a year in a small circle gives wealth and spirit to its inhabitants. We do not see, however clearly we may infer it, that so much the less is expended in Manchester, Birmingham, or Leeds. The inhabitants of his village attribute their gain and their loss to its causes; and their complaints and acknowledgments are loud in proportion to the degree in which they feel their interests to be affected. No single manufacturer is conscious that the average annual export of more than forty millions sterling has been increased or diminished to the amount of £2000 or £3000. And even if aware of that increase or diminution, he would not attribute it to the residence in Yorkshire or Paris of a given individual, of whose existence he probably is not aware. When to obvious and palpable effects nothing is to be opposed but inferences deduced by a long, though perfectly demonstrative, reasoning process, no one can doubt which will prevail, both with the uneducated, and the educated, vulgar.

Many persons, also, are perplexed by the consideration, that all the commodities which are exported as remittances of the absentee's income are exports for which no return is obtained; that they are as much lost to this Country as if they were a tribute paid to a foreign State, or even as if they were thrown periodically into the sea. This is unquestionably true; but it must be recollected, that whatever is unproductively consumed is, by the very terms of the proposition, destroyed, without producing any return. The only difference between the two cases is, that the resident landlord performs that destruction here; the absentee performs it abroad. In either case, he first purchases the services of those who produce the things which he, for his benefit, not for theirs, is to consume. If he stays here, he pays a man to brush a coat, or clean a pair of boots, or arrange a table; all which in an hour after are in their former condition. When abroad, he pays an equal sum for the production of needles, or calicoes, which are sent abroad, and equally consumed without further benefit to those who produced them. They are, in fact, sold for money to be employed in paying the wages of those foreign servants who now brush the shoes and draw the corks, which, if the landlord had not been an absentee, would have been brushed and drawn in England. The income of unproductive consumers, however paid, is a tribute; and whether they enjoy it here or elsewhere, is their own concern. We know that a man cannot eat his cake and have it; and it is equally true that he cannot sell a cake to another and keep it for himself.

Again, some acute reasoners appear to us to have been led into error on this subject, by perceiving that the income of an absentee is generally remitted to him by means of a trade in which the returns are comparatively slow,* and that the expenditure of his income is profitable to those among whom he resides.† Now assuming that these circumstances occasion a loss to any body, it is clear that the loss falls solely on the absentee. His rents are, in the first instance, expended as quickly as they are received in the purchase of manufactured commodities, to be exported for his benefit as a means of remittance. They are expended, therefore, in the support of the trade of the English manufacturer, a trade giving quick returns, high wages, and, if we may judge from the additional capital which it is attracting every day, high profits. The absentee, in thus spending his income, gives to England all that an unproductive consumer *can* give, the wages and the profits arising from the expenditure in England of his income as fast as he receives it. Neither the gain nor the loss attending on the remittance or on the subsequent expenditure of its amount are any concern of ours. They affect only the absentee. If he selects ill the place of his residence, he may have to lose by remittances at long dates, or at an unfavourable exchange, or have to pay dearly for bad commodities or unskilful services. If he selects it well, he may be a gainer by the intermediate operations to which his income has been subjected, and receive a larger revenue than he would have obtained at home, or may spend that revenue more agreeably. But with all this England has nothing to do.

The last cause to which we attribute the slow progress of correct opinions on this subject is their distastefulness to the most influential members of the community. Nothing can be more flattering to landlords, annuitants, mortgagees, and fundholders, than to be told that their residence is of vital importance to the Country. Nothing can be more humiliating than to be assured that it is utterly immaterial to the rest of the community whether they live in Brighton, or London, or Paris. Those who are aware how much our judgment, even in matters of Science, is influenced by our wishes, will not be surprised at the prejudices against a doctrine which forbids the bulk of the educated class to believe that they are benefactors to their Country by the mere act of residing within its shores.

We may appear, perhaps, to have dwelt too much on a single subject; but no prevalent error can be effectually exposed until its prevalence has been accounted for. And these are errors which are to be heard in every society, and often from those whose general views in Political Economy are correct. They may be called harmless errors, but no error is, in fact, harmless; and when there is so much in our habits that really requires alteration, we may lose sight of the real and the remediable causes of evil, while our attention is misdirected to absenteeism.

Machines.

Fourthly. Our proposition that the rate of wages depends on the extent of the fund for the maintenance of labourers, compared with the number of labourers to be maintained, is inconsistent with the *doctrine that the general rate of wages can*, except in two cases, *be diminished by the introduction of machinery.*

The two cases in which the introduction of machinery can produce such an effect are, first, when labour is employed in the *construction* of machinery, which labour would otherwise have been employed in the production of commodities for the use of labourers; and, secondly, when the machine itself consumes commodities which would otherwise have been consumed by labourers, and *that* to a greater extent than it produces them.

The first case is put by Mr. Ricardo, in his chapter on machinery; but in so detailed a form, that, instead of quoting it, we will extract its substance, with a slight variation of the terms. He supposes a capitalist to carry on the business of a manufacturer of commodities for the use of labourers; or, to use a more concise expression, the business of a manufacturer of wages. He supposes him to have been in the habit of commencing every year with a capital consisting of wages for a certain number of labourers, which we call twenty-six, and of employing that capital in hiring twenty men, to reproduce, during the year, wages for the whole twenty-six, and six to produce commodities for himself. He now supposes him to employ ten of his men during a year in producing, not wages, but a machine, which, with the aid of seven men to keep it in repair and work it, will produce every year wages for thirteen men; that is, wages for six men besides the seven that work it. At the end of the year the capitalist's situation would be unaltered: he would have wages for thirteen men, the produce of the labour of his other ten men during the year; and his machine, also the produce of the labour of ten men during the year, and therefore of equal value. And his situation would *continue* unaltered. Every year his machine would produce wages for thirteen men, of whom seven must be employed in repairing and working it, and six might, as before, be employed for the benefit of the capitalist. But we have seen that, *during the year in which the machine was constructed*, only ten men were employed in producing wages instead of twenty, and, consequently, that wages were produced for only thirteen men instead of for twenty-six. At the end of that year, therefore, the fund for the maintenance of labour was diminished, and wages must, consequently, have fallen. It is of great importance to recollect, that the only reason for this fall was the diminution of the annual production. The twenty men produced wages for twenty-six men: the machine produces wages for only thirteen. The vulgar error on this subject supposes the evil to arise, not from its true cause, the expense of constructing the machine, but from the productive powers of that machine. So far is this from being true, that those productive powers are the specific benefit which is to be set against the evil of its expensiveness. If, instead of wages for thirteen men, the machine could produce wages for thirty, its use, as soon as it came into operation, would have increased instead of diminishing the fund for the maintenance of labour. The same effect would have been produced, if the machine could have been obtained without expense; or if the capitalist, instead of building it out of his capital, had built it out of his profits; if, instead of withdrawing ten men for a year from the production of wages, he had employed in its construction, during two years, five of the men whom he is supposed to have employed in producing commodities for his own use. In either case, the additional produce obtained from the machine would have been an additional fund for the maintenance, of labour; and wages must, according to our elementary proposition, have risen.

---

* Professor Longfield, *Lectures on Commerce and Absenteeism*, p. 6.

† Carey *on Wages*, p. 46. A Work which we regret not to have received until part of this Treatise had been stereotyped, and the remainder was in print.

We have thought it necessary to state this possible evil as a part of the theory of machinery, but we are far from attaching any practical importance to it. We do not believe that there exists upon record a single instance in which the whole annual produce has been diminished by the use of *inanimate* machinery. Partly in consequence of the expense of constructing the greater part of machinery being defrayed out of profits or rent, and partly in consequence of the great proportion which the productive powers of machinery bear to the expense of its construction, its use is uniformly accompanied by an enormous *increase* of production. The annual consumption of cotton wool in this Country, before the introduction of the spinning-jenny, did not exceed twelve hundred thousand pounds; it now amounts to two hundred and forty millions. The number of copies of books extant at any one period before the invention of the printing-press was probably smaller than that which is now produced in a single day. Mr. Ricardo's proposition, therefore, (*Princ.* 474.) that the use of machinery *frequently* diminishes the quantity of the gross produce of a Country, is erroneous, so far as it depends on the case which he has supposed, and of which we have stated the substance.

The other exception, that where the machine itself consumes commodities which would otherwise have been consumed by labourers, and that to a greater extent than it produces them, applies only to the case of horses and working-cattle, which may be termed animated machines. We will suppose a farmer to employ on his farm twenty men, who produce annually their own subsistence, and that of six other men producing commodities for the use of their master. If five horses, consuming, we will say, as much as eight men, could do the work of ten men, it would be worth the farmer's while to substitute them for eight of his men, as he would be able to increase the number of persons who work for his own benefit from six to eight. But after deducting the subsistence of the horses, the fund for the maintenance of labourers would be reduced from wages for twenty-six men to wages for eighteen. We cannot refuse to admit that such cases may exist, or to deplore the misery that must accompany them. They are, in fact, now occurring in Ireland, and are occasioning much of the distress of that Country. They seem, indeed, to be the natural accompaniments of a certain period in the progress of national improvement. In the early stages of society, the rank and even the safety of the landed proprietor is principally determined by the number of his dependents. The best mode of increasing that number is to allow the land, which he does not occupy as his own demesne, to be subdivided into small tenements, each cultivated by one family, and just sufficient for their support. Such tenants can of course pay little rent, but they are enabled by their abundant leisure, and forced by their absolute dependence, to swell the retinue, and aid the political influence, of their landlord in peace, and to follow his banner in public and private war. Cameron of Lochiel, whose rental did not exceed £500 a year, carried with him into the Rebellion of 1745 eight hundred men raised from his own tenantry. But in the progress of civilization, as wealth becomes the principal means of distinction and influence, landowners prefer rent to dependents. To obtain rent, that process of cultivation must be employed which will give, not absolutely the greatest amount of produce, but the greatest after deducting the expenses. For this purpose a tract of five hundred acres, from which fifty families produced their own subsistence, and produced scarcely any thing more, may be converted into one farm, and with the labour of ten families, and as many horses, may produce the subsistence of only thirty families. Fortunately, however, the period at which these alterations take place is generally one of great social improvement; so that, after a short interval, the increased diligence and skill with which labour is applied occasion an increase of the produce, after deducting the new expenditure. The fund for the maintenance of labourers now becomes increased from two different sources—partly from the increased efficiency of human labour when aided by that of horses and cattle, and partly from the results of a part of the human labour set free by the substitution of brutes. The ultimate consequences of such a change are always beneficial; the change itself must, in general, be accompanied by distress.

But with the exception of these two cases, one of which produces only temporary effects, and the other, though apparently possible, seems never actually to occur, it appears clear that the use of machinery must either raise the general rate of wages, or leave it unaltered.

When machinery is applied to the production of commodities which are *not* intended, directly or indirectly, for the use of labourers, it occasions no alteration in the general rate of wages; we say the *general* rate of wages, because it may diminish the rate of wages in some employments,—a diminution always compensated by a corresponding increase in some others. A small screw was shown to us at Birmingham which, in the manufacture of corkscrews, performed the work of fifty-nine men; with its assistance one man could cut a spiral groove in as many corkscrew shanks as sixty men could have cut in the same time with the tools previously in use. As the use of corkscrews is limited, it is not probable that the demand for them has sufficiently increased to enable the whole number of labourers previously employed in their manufacture to remain so employed after such an increase in their productive power. Some of the corkscrew-makers, therefore, must have been thrown out of work, and the rate of wages in that trade probably fell. But as the whole fund for the maintenance of labourers, and the whole number of labourers to be maintained, remained unaltered, that fall must have been balanced by a rise somewhere else—a rise which we may trace to its proximate cause, by recollecting that the fall in the price of corkscrews must have left every purchaser of a corkscrew a fund for the purchase of labour, rather larger than he would have possessed if he had paid the former price.

If, however, machinery be applied to the production of any commodity used by the labouring population, the general rate of wages will *rise*. That it cannot fall is clear, on the grounds which we have just stated. If the improvement be great, and the commodity not subject to a corresponding increase of demand, some of the labourers formerly employed in its production will be thrown out of employment, and wages, in that trade, will fall—a fall which, as the whole fund for the maintenance of labour is not diminished, must be met by a corresponding rise in some other trade. But the fund *will be increased* by the additional quantity produced of the commodity to which the improvement has been applied: estimated in that commodity, therefore, the general rate of wages, or, in other words, the quantity of commodities obtained by the labouring population, will be increased by the introduction of machinery; estimated in all others, it will be stationary.

The example taken from the manufacture of corkscrews is as unfavourable to the effects of machinery as can be proposed; for the use of the commodity is supposed to be unable to keep up with the increased power of production, and the whole number of labourers employed on it is, consequently, diminished. This, however, is a very rare occurrence. The usual effect of an increase in the facility of producing a commodity is so to increase its consumption as to occasion the employment of more, not less, labour than before.

We have already called the reader's attention to the effects of machinery in the manufacture of cotton and in printing. Each of these trades probably employs ten times as many labourers as it would have employed if spinning-jennies and types had not been invented. Under such circumstances, (and they are the usual ones,) the benefits of machinery are not alloyed by even partial inconvenience.

Those who are little affected by inferences from general propositions may be influenced by a witness who states the results of his own observations. We will support our argument, therefore, by the following extract from Mr. Cowell's valuable preface to the tables of wages constructed by him in the performance of his duties as a Commissioner on the Factory Inquiry:—

"As long as the cotton-working continues to extend, the apprehensions entertained by the operatives of a fall in wages, either for adults or children, consequent upon improvements in machinery, are groundless. Their assertion is, (and it was repeated to me innumerable times,) that they have to turn out more work now for less wages than formerly. The *Manchester and Salford Advertiser*, which is the journal of the operatives, scarcely publishes a number which does not ring the changes on this assertion; and in that for the 11th of January, 1834, it asserts, 'that a spinner now turns out double the work for a tenth less wages than in 1804.'

"The matter stands thus: in 1804 a spinner was paid 8*s*. 6*d*. for every pound of yarn of the fineness of two hundred hanks to the pound, spinning on a mule of the average productive power of that time. What that productive power was I do not know. But in 1829 he was paid at the rate of 4*s*. 1*d*. for spinning the same quality on a mule of the productive power of three hundred and twelve; in 1831, and at present, at the rate of 2*s*. 5*d*, and 2*s*. 8½*d*. for spinning the same quality on a mule of the productive power of six hundred and forty-eight. These quotations are from the Manchester prices.

"Thus, in 1829, the spinner turned off three hundred and twelve pounds of yarn in the same time that he now takes to turn off six hundred and forty-eight. He was paid at the rate of 4*s*. 1*d*. per pound in 1829, he is now paid at the rate of 2*s*. 5*d*. But three hundred and twelve pounds at 4*s*. 1*d*. amount to one thousand two hundred and seventy-four shillings, and six hundred and forty-eight pounds at 2*s*. 5*d*. to one thousand five hundred and sixty-six shillings. He receives, therefore, two hundred and ninety-two shillings more than he did in 1829 for equal times of work. It is perfectly true that he does 'more work for less wages than in 1829;' but this is nothing to the purpose, when the proposition to be proved is, that 'wages are lower than formerly.' I mean to say, that a spinner earns a shilling, or a pound, or a hundred pounds, in less time at present than he would have consumed in earning a shilling, or a pound, or a hundred pounds, ten years ago, and with the same or less labour; that this enhancement of his earnings has been owing to improvements in machinery; that the progress of improvements will progressively advance his earnings still higher, and at the same time enable a greater number of individuals to profit by the enhanced rate than actually profits by the actual rate; (provided that nothing occurs to prevent the cotton business from developing itself for the next thirty years as it has done for the last;) and that any improvement in the machinery in any one of the numerous departments of cotton-working will operate to enhance the rate of wages in all other branches, (as well as in that department in which it takes place,) by increasing the actual previous demand for labour in those other branches. I assert that every improvement of cotton machinery, in any department of cotton-working, has hitherto had the effect of enabling 'an operative' (speaking in general of every one, in every department whatever) to earn a greater net amount of money, in any given time, than he would have done if the improvements had never taken place.

"The misconceptions as to the real effect of machinery on the wages of labour which the operatives entertain are the causes of turn-outs and strikes; they produce rankling discontent towards their masters, and I regret that I have not had the opportunity of giving them a fuller exposure.

"I certainly consider it of great consequence that the operatives themselves should be satisfied that improvements in machinery tend to raise the amount of money that they gain individually and generally, for the same number of hours' work. Those who dispute the fact must, I think, admit that I have established it in the cases which I have selected, as far as *spinners* are concerned; and as they must likewise admit that the improvement specified creates a fresh and additional demand for young hands, they must also admit that the wages of young hands are augmented in consequence. They must equally admit, that as the price of the article will be lowered in the market from the effects of the improvement, more of it will be consumed; and hence that, in all the correlate processes connected with spinning of cotton, more hands will be required, and consequently that wages throughout the whole range of cotton-working will be better than they were before. If these considerations should induce operatives to hesitate before they combine and turn out against new machinery, before they again cabal for shortening the hours of work, in order to counteract the (fancied) injurious effect upon wages of improvements in machinery, and should lead them to neglect the advice of those who urge them 'to strike for eight hours' work and twelve hours' earnings,' (and this is the advice they have lately received,) my purpose will be answered.

"The generality of the operatives in cotton-working are well meaning, respectable, shrewd, and sensible; and I believe that if the real effect of machinery in augmenting the actual rate of their earnings, and in enabling a greater number of persons to benefit by the augmented rate, could be fairly set before them and rendered familiar to their minds, it would have a most beneficial effect upon their actions as members of society." *Factory Inquiry Commission*, 2d Report. D. i. 119. n. m.

Population.

Fifthly. Closely connected with this mistake, and occasioned by the same habit of attending only to what is temporary and partial, and neglecting what is permanent and general; of dwelling on the evil that is concentrated, and being insensible to the benefit that is diffused, is the common error of supposing *that the general rate of wages can be reduced by the importation of foreign commodities.* In fact, the opening of a new market is precisely analogous to the introduction of a new machine, except that it is a machine which it costs nothing to construct or to keep up. If the foreign commodity be not consumed by the labouring population, its introduction leaves the general rate of wages unaffected; if it be used by them, their wages are raised as estimated in that commodity. If the laws which favour the wines of the Cape to the exclusion of those of France were repealed, more labourers would be employed in producing commodities for the French market, and fewer for that of the Cape. Wages might temporarily fall in the one trade, and rise in the other. The clear benefit would be derived by the drinkers of wine, who, at the same expense, would obtain more or better wine. So if what are called the protecting duties on French silks were removed, fewer labourers would be employed in the direct production of silk, and more in its indirect production, by the production of the cottons or hardware with which it would be purchased. The wearers of silk would be the only class ultimately benefited; and as the labouring population neither wear silk nor drink wine, the general rate of wages would, in both cases, remain unaltered. But if the laws which prohibit our obtaining on the most advantageous terms sugar and corn were altered, that portion of the fund for the maintenance of labour, which consists of corn and sugar, would be increased. And the general rate of wages, as estimated in two of the most important articles of food, would be raised.

Employment.

Sixthly. The views which we have been endeavouring to explain are inconsistent with the common opinion, *that the unproductive consumption of landlords and capitalists is beneficial to the labouring classes, because it furnishes them with employment.* "Tillage," says Paley, (and this is another form of the same fallacy,) "is preferable to pasturage, not only because the provision which it yields goes much further in the sustentation of life, but because it affords *employment* to a more numerous peasantry." The production of more subsistence is certainly an advantage, but what is the advantage of its requiring more labour? If this be an advantage the fertility of land is an evil. If the thing required be *employment*, we should abandon ploughs and even spades. To scratch up a rood with the fingers would give more employment than to dig an acre. Those who maintain that unproductive consumption does good by affording employment, must forget that it is not employment, but food, clothing, shelter, and fuel, in short, the materials of subsistence and comfort, that the labouring classes require. The word "employment" is merely a concise form of designating toil, trouble, exposure, and fatigue. It is indeed sometimes elliptically used as implying the subsistence which is purchased by enduring it. A poor man complains that he wants *work*. He might work to his heart's content, and with no man's leave, if he chose to carry stones from the bottom to the top of a hill. But what he wants is work as a means of obtaining payment. He would be happy to get the payment without the work. Toil, exposure, and fatigue, *per se*, are evils, and the less of them that is required for obtaining a given amount of subsistence and comfort, or, in other words, the greater the facility of obtaining that given amount, the better, *cæteris paribus*, will be the condition of the labouring classes; indeed, of all classes in the community. What occasions the prosperity of a colony? Not the dearness of subsistence, but its cheapness; not the difficulty of obtaining food, clothing, shelter, and fuel, but the facility. Now how can unproductive consumption increase this facility? How can the fund from which all are to be maintained be augmented by the destruction of a portion of it? If the higher orders were to return to the customs of a century ago, and cover their coats with gold

Distribution. Wages. Erroneous opinions. Employment.

lace, they might enjoy their own finery; but how would that benefit their inferiors? The theory which we are considering replies that they would be benefited by being *employed* in making the lace. It is true that a coat, instead of costing £5, would cost £55. But what becomes *now* of the extra £50? for it cannot be said that, because it is not spent on a laced coat, it does not exist. If a landlord with £10,000 a year spends it unproductively, he pays it away to those who furnish the embellishments of his house and grounds, and supply his stable, his equipage, and his clothes. Suppose him now to abandon all unproductive expenditure, to confine himself to bare necessaries, and to earn them by his own labour, the first consequence would be, that those among whom he previously spent his £10,000 a year would lose him as an employer; and beyond this the theory in question sees nothing. But what would he do with the £10,000 which he would still annually receive? No one supposes that he would lock it up in a box, or bury it in his garden. Whether productively or unproductively, it still must be spent. If spent by himself, as by the supposition it would be spent productively, it must increase, and every year still further increase, the whole fund applicable to the use of the rest of the community. If not spent by himself, it must be lent, as is done by a miser of the present day, to some other person, and by that person it must be spent productively or unproductively. He might, perhaps, buy with it property in the English funds; but what becomes of it in the hands of the person who sells to him that funded property? He might buy with it French rentes; but in what form would the price of those rentes go to Paris?—In the form, as we have seen, of manufactured commodities. *Quâcunque viâ datâ*, every man must spend his income; and the less he spends on himself, the more remains for the rest of the world.

The seventh and last theory inconsistent with our own views, to which we shall call the reader's attention, is that proposed by Mr. Ricardo in the following passage:—

Preference of services to commodities.

"The labouring class have no small interest in the manner in which the net income of the Country is expended, although it should, in all cases, be expended for the gratification and enjoyment of those who are fairly entitled to it.

"If a landlord, or a capitalist, expends his revenue in the manner of an ancient Baron, in the support of a great number of retainers or menial servants, he will give employment to much more labour than if he expended it on fine clothes or costly furniture.

"In both cases the net revenue would be the same, and so would be the gross revenue, but the former would be realized in different commodities. If my revenue were £10,000, the same quantity nearly of productive labour would be employed, whether I realized it in fine clothes and costly furniture, &c. &c., or in a quantity of food and clothing of the same value. If, however, I realized my revenue in the first set of commodities, no more labour would be *consequently* employed: I should enjoy my furniture and my clothes, and there would be an end of them; but if I realized my revenue in food and clothing, and my desire was to employ menial servants, all those whom I could so employ with my revenue of £10,000, or with the food and clothing which it would purchase, would be to be added to the former demand for labourers, and this addition would take place only because I chose this mode of expending my revenue. As the labourers, then, are interested in the demand for labour, they must naturally desire that as much as possible should be diverted from expenditure on luxuries, to be expended in the support of menial servants.

"In the same manner a Country engaged in war, and which is under the necessity of maintaining large fleets and armies, employs a great many more men than will be employed when the war terminates, and the annual expenses which it brings with it cease.

"If I were not called upon for a tax of £500 during the war, which is expended on men in the situations of soldiers and sailors, I might probably spend that portion of my income on furniture, clothes, books, &c. &c., and whether it was expended in the one way or the other, there would be the same quantity of labour employed in production; for the food and clothing of the soldier and sailor would require the same amount of industry to produce them as the more luxurious commodities: but, in the case of war, there would be the additional demand for men as soldiers and sailors; and, consequently, a war which is supported out of the revenue, and not from the capital of a Country, is favourable to an increase of population.

"At the termination of the war, when part of my revenue reverts to me, and is employed as before in the purchase of wine, furniture, or other luxuries, the population which it before supported, and which the war called into existence, will become redundant, and by its effect on the rest of the population, and its competition with it for employment, will sink the value of wages, and very materially deteriorate the condition of the labouring classes."*

Mr. Ricardo's theory is, that it is more beneficial to the labouring classes to be employed in the production of services than in the production of commodities; that it is better for them to be employed in standing behind chairs than in making chairs; as soldiers or sailors than as manufacturers. Now, as it is clear that the whole quantity of commodities provided for the use of labourers is not increased by the conversion of an artisan into a footman or a soldier, either Mr. Ricardo must be wrong, or our elementary proposition is false.

Mr. Ricardo seems to have been led to his conclusions by observing that the wages of servants, sailors, and soldiers are principally paid in kind—those of artisans in money. He correctly states, that if a man with £10,000 a year spends his income in the purchase of commodities for his own use, he retains, after having made those purchases, no further fund for the maintenance of labour; but that if he spends it in the purchase of commodities to be employed in maintaining menial servants, he has, in those purchased commodities, a new fund with which he can maintain a certain number of menial servants. It appeared to him, therefore, that the landlord would, in the latter case, be able to spend his income twice over; to subsist twice as many persons as before. It did not occur to him that the landlord, by purchasing himself the subsistence of his servants, merely does for them what they would be able to do better for themselves; that, instead of spending his own income twice over, he merely takes on himself the business of spending theirs for them. He did not perceive that all that the landlord spends in purchasing the subsistence and clothing of his servants, is so much deducted from what he would otherwise have to pay to

---

* *Principles, &c.* p. 475.

Erroneous opinions. Preferment of services to commodities.

them in money, to be by them employed in the purchase of subsistence and clothing; and that if he were to give to his servants the value of their whole subsistence in money, the whole body of labourers would be just as well maintained as in the supposed case of his purchasing their subsistence, and then giving it to them in exchange for their services. No one would maintain that, if it were the general practice, in this Country, as it is in India, to give to servants board wages, the demand for labour would be lessened; or that if it were the practice, as it is in semi-barbarous Countries, to maintain servants to produce within their masters' walls the commodities which we are accustomed to purchase from shops, such as the fine clothes and furniture to which Mr. Ricardo alludes, the demand for labour would be increased. Still less could it be maintained, that if those servants, instead of producing commodities, were employed in following their master's person, or mounting guard before his door, such a change would create an additional demand for men, and be favourable to an increase of population.

So far are we from concurring in Mr. Ricardo's opinion, that it is the interest of the labourers that revenue should be spent rather on services than on commodities, that we believe their interest to be precisely opposite. In the first place, the labourer can generally manage better his own income than it can be managed for him by his master. If a domestic servant could earn as wages the whole sum which he costs his master, even if he were to spend it as he received it, he would probably spend it with more enjoyment. Secondly, the income spent on services is generally spent in the purchase of what perishes at the instant of its creation; that spent on commodities often leaves results which, when their first purchaser has done with them, are serviceable to others. In this Country the poor are, to a great extent, clothed with garments originally provided for their superiors. In all the better class of cottages may be found articles of furniture which never could have been made for their present possessors. A large portion of the commodities which now contribute to the comfort of the labouring classes would never have existed if it had been the fashion in this Country, during the last fifty years, to prefer retinue and attendance to durable commodities. And, thirdly, the income employed on commodities is favourable to the creation of both material and immaterial capital; that employed on services is not. The duties of a servant are so easily learned, that he can scarcely be termed a skilled labourer; his accumulations are small in amount, and seldom turned to much advantage. The artisan learns a trade, in which every year adds to his skill, and is taught mechanical and chemical processes, often susceptible of indefinite improvement, and in which a single invention may raise the author to wealth, and diffuse prosperity over a whole district, or even a whole nation. An industrious artisan can often save a large portion of his income, and invest it with great and immediate profit. He purchases with his savings a small stock of tools and materials, and, by the vigilance and activity which can be applied only to a small capital, renders every portion of it efficient. The ancestors, and not the remote ancestors, of some of our richest and our proudest families, the authors of some of our most valuable discoveries, were common mechanics. What menial servant has in this Country, and in modern times, been a public benefactor, or even raised himself to affluence? Both history and observation show that those Countries in which expenditure is chiefly employed in the purchase of services are poor, and those in which it is chiefly employed on commodities are rich.

Mr. Ricardo's theory as to the effects of war is still more strikingly erroneous. It is, in the first place, open to all the objections which we have already opposed to his views respecting menial servants. The revenue which is employed in maintaining soldiers and sailors would, even if unproductively consumed, maintain at least an equal number of servants and artisans; and that portion of it which would have been employed in the maintenance of artisans would (as we have seen) have been far more beneficially employed. The demand for soldiers and sailors is not, as he terms it, an additional, it is merely a substituted, demand. But a great part of that revenue would have been productively consumed. Instead of employing some labourers in converting suburbs into fortifications, and forests into navies, to perish by dry rot in harbour, or by exposure at sea, and others in walking the deck and parading on the rampart, it would have employed them in adding more and more every year to the fund from which their subsistence is derived. War is mischievous to every class in the community; but to none is it such a curse as to the labourers.

We have now explained the principal errors which are inconsistent with our elementary proposition, namely, that *the quantity and quality of the commodities obtained by each labouring family during the year must depend on the quantity and quality of the commodities directly or indirectly appropriated during the year to the use of the labouring population, compared with the number of labouring families, or, to speak more concisely, on the extent of the fund for the maintenance of labourers, compared with the number of labourers to be maintained.*

On what, then, does the extent of that fund depend? In the first place, on the productiveness of labour in the direct or indirect production of the commodities used by the labourer; and, in the second place, on the number of persons directly or indirectly employed in the production of things for the use of labourers, compared with the whole number of labouring families. If we wished to ascertain the comparative wages of the labouring population in two parishes, containing each, we will say, twenty-four labouring families, these are the only two points to which we need direct our inquiries. If we found that in the one parish eighteen families, and in the other only twelve, were employed in producing commodities for the whole twenty-four, we should infer that, supposing the labour of each to be equally productive, wages must be higher by one-fourth in the first than in the second. But if we found that in the second parish labour was more productive by one-half than in the first, we should infer an equality of wages in the two.

Productiveness of labour.

We will begin by considering the causes which affect the productiveness of labour in the direct or indirect production of the commodities, used by the labourer. We add the word *indirect*, not with reference to the whole fund which supplies the maintenance of all the labourers throughout the world, but with reference to the fund which supplies the wants of the labourers in a particular Country. If we consider the whole world as forming one community, it is obvious that the fund for the subsistence of the labouring por-

Political Economy.

Distribution. Wages. Productiveness of labour.

tion of that community cannot be increased by the increased production of those commodities which they do not use; by the increased production, for instance, of lace or statues.

But the fund for the maintenance of the labourers in any given Country may be, and often is, materially dependent on the facility with which they can produce commodities useless to themselves except as the instruments of exchange. The tea, the tobacco, and the sugar used by our labouring population are principally obtained in return for exported commodities unfitted for our climate and our habits. But the superior facility with which we produce those exported commodities enables, or, if legislative interference did not prevent it, would enable, our labouring population to obtain tea, sugar, and tobacco with less labour than they cost in the Countries of which they are the natural growth. It is unimportant to the labourer whether his corn is the produce of the soil of England or of Poland; whether it is obtained directly by means of the plough, or indirectly by means of the loom.

On what then does the first of these two causes, namely, the productiveness of labour, depend?

First. It depends partly on the corporeal, intellectual, and moral qualities of the labourer; on his diligence, his skill, and his strength of body and mind. And these depend on causes, many of which are imperfectly understood, and others are too complicated to admit of concise explanation, or to be fully considered without entering into investigations connected indeed with Political Economy, but not within its peculiar province. Much may depend on race and on climate; much more depends on religion, education, and government. One cause only we shall slightly dwell on, because it is simple, and has not been sufficiently considered by any writers except M. Quetelet,[*] and Sir F. D'Ivernois,[†] and that is, the mean age of the labouring population. This depends partly on the average duration of life in a Country, and partly on the rate at which its population is increasing. In England, the average duration of life is supposed to amount to about forty-four years. In many Countries it does not reach thirty-five; in some it does not attain twenty-five. Again, in some Countries the population doubles every twenty-five years. At the present rate of increase in England it would double in about fifty. The average period of its doubling throughout Europe is supposed to be about a century.

Now it is obvious that, the number of persons and the rate of increase in any two Countries being given, that Country would have the greater number of adults in which the average duration of life was the longer; and, the longevity being given, that Country would have the greater proportion of adults in which the rate of increase was the slower. Longevity, and a population stationary or slowly increasing, are therefore favourable to the productiveness of labour.

Secondly. The corporeal, intellectual, and moral qualities of the labourer being given, the productiveness of labour in any Country will partly depend on the natural agents by which it is assisted, or, in other words, on the climate, soil, situation, and extent in proportion to its population, of that Country.

To some Countries nature has refused the means of supporting human life; to others she has refused the means of wealth. No exertions would enable a community to exist long on Melville Island, or in the Deserts of Africa, or to exist comfortably in Greenland or Nova Zembla. But, though she can deny riches, she cannot give them. The finest districts in the world are among the poorest. With all the brute and inanimate sources of affluence profusely scattered before them, the inhabitants of the greater part of Africa, America, and Asia want the moral and intellectual qualities by which the raw materials of wealth are to be worked up. Even the Iceland ersseem to be richer than the Guachos. But, although local advantages are far from being the most efficient causes of the productiveness of labour, their influence must not be disregarded. They have enabled the colonies of highly civilized nations to advance to opulence with a rapidity of which we have no other example.

Political Economy.

Distribution. Wages. Productiveness of labour.

Thirdly. The productiveness of labour partly depends on the degree in which it is assisted by abstinence, or, to use a more familiar expression, by the use of capital.

We have already explained the advantages afforded by capital, and traced them to the use of implements and the division of labour, and need only remind our readers that, of all means by which labour can be rendered productive, the use of capital is far the most efficient. Without tools, and without the division of employments, man would be an animal less capable of obtaining enjoyment, or even subsistence, than the brutes of the field.

Fourthly. The last of the causes which influence the productiveness of labour is the existence or the absence of government interference.

The essential business of government is to afford defence; to protect the community against foreign and domestic violence and fraud. Unfortunately, however, governments have generally supposed it to be their duty, not merely to give *security* but *wealth*; not merely to enable their subjects to produce and enjoy in safety, but to teach them *what* to produce and *how* to enjoy; to give them instruction how to manage their own concerns, and to force them to obey that instruction.

Unfortunately, too, the ignorance and folly with which they have attempted to execute this office have been equal to the ignorance and folly which led them to undertake it. Partly under the influence of what has been called the mercantile theory, the theory which teaches that wealth consists of gold and silver, and may be indefinitely increased by exporting commodities, and receiving only money in return; and partly misled by the circumstance, that when an individual, or a class, obtains a monopoly against the public, the loss, however great, becomes imperceptible from its diffusion, and the gain, however trifling, is obvious, because it is concentrated, it has long been the ruling principle of commercial statesmen to favour direct at the expense of indirect production; to refuse participation in the benefits bestowed by nature on foreign Countries, though at the expense of surrendering a portion of what she has conferred on their own; and to force the industry of their subjects from those channels in which they have peculiar advantages, into those for which their climate, their habits, and their soil are inappropriate.

It is under the influence of these causes that the civilized world has lately exhibited the strange spectacle of general peace accompanied by general distress. During the War, the greater part of Southern Europe had coalesced into one vast Empire; a single Sovereign ruled from Hamburgh to Rome; and hundreds of lines of custom-houses and revenue-officers, that had previously interposed against commerce barriers more impassable than seas or mountains, were swept away. Napoleon was deeply steeped in the mercantile theory, and his conduct shows how completely his views were founded on unreflecting prejudice. In obedience to that theory, he believed free trade between independent States to be like gambling between individuals, and therefore mischievous to the one or to the other: mischievous in fact to the one which, in the ultimate settling of accounts, had to pay a balance in money. While France and Italy were under different rulers, he therefore must have believed that the inhabitants of one of the two Countries would be injured by being allowed to purchase the commodities of the other. But the framers of the mercantile theory, blind as they were, had never ventured to object to the freest intercourse between the inhabitants of contiguous districts in the same Empire. When he had forced under his yoke Belgium and France, he allowed them therefore a freedom of intercourse which he still prohibited between France and Austria; totally forgetting that the benefit of an exchange does not depend on the accident, whether the parties to it are, or are not, fellow-subjects. His theories were servile copies of errors unhappily too prevalent, and faded away before his strong common sense on the slightest variation of appearances, though the facts on which the question turns were unaltered.

---

[*] *Sur l'Homme*, tome i. p. 324.

[†] *Sur la Mortalité Proportionelle*, &c.

On the termination of the War, Napoleon's Empire was broken up into independent Kingdoms, and each State set to work to reimpose on itself the fetters which his powerful hand had broken. Douaniers and preventive-service men were found instruments as efficient in wasting the resources of their own Country, and in arresting the improvement of their neighbours, as armies and fleets. The produce of France became contraband in Belgium and Italy, and the produce of Belgium and Italy in France. America solemnized the Peace by a tariff, and England by a corn law. To prohibit whatever is wanted became again the rule in commercial policy. Russia is an agricultural Country; she therefore forbad the import of foreign manufactures. England is abundantly supplied with manufactures, she therefore prohibited corn.

We are inclined to think that the conduct of Russia was practically more mischievous than that of England. She has adhered to the anti-commercial system with far more pertinacity than we have; indeed, every change which she has made, has been to add to duties, and to extend prohibitions. But the objections in principle against the exclusion of raw produce seem to us still more forcible than those against the exclusion of manufactures. In the first place, the consumption of the labourer consists principally of raw produce, or slightly worked commodities. No restrictions on the importation of the finer manufactures can affect him. But laws against the importation of raw produce are specifically directed against the labouring population. Their professed object is to diminish, in fact, the principal fund for the maintenance of labour. And, secondly, when an agricultural Country prohibits foreign manufactures, the labourer is, to a certain extent, indemnified by a consequent fall in the price of raw produce. On the other hand, when a manufacturing Country prohibits the importation of raw produce, the price of all commodities, excepting labour, has a tendency to increase, and the labourer finds it more difficult to obtain *every* article of his consumption.

This may require some explanation. We have already shown, that every additional quantity of raw produce is, generally speaking, obtained at a greater proportional expense. To prohibit the importation of manufactures is, of course, to prohibit the exportation of the raw produce, which otherwise would have been employed in purchasing them. As a smaller quantity of raw produce is wanted, a smaller quantity is produced, and that quantity is produced at a less proportionate expense; labour, though less productive in clothes and furniture, becomes more productive in raw produce; the price of raw produce, therefore, falls, and the labourer, in having less to pay for food, obtains some compensation for having more to pay for other commodities. The greater part of the evil falls on the proprietors of the land. On the contrary, every additional quantity of manufactured produce is obtained, so far as the manufacturing of it is concerned, at a less proportionate expense. Every increase of the supply is accompanied by the introduction of more and better machinery, and by a further division of labour. As in the former case, restrictions on the importation of raw produce are, in fact, restrictions on the exportation of manufactures. Fewer manufactured commodities being wanted, and consequently fewer produced, what are produced are produced at the expense of proportionately more labour than would otherwise be necessary. More raw produce must be raised at home, and that also must be raised at a greater proportionate expense of labour. The price of the one kind of commodities rises, because it has become necessary to produce more, and that of the other, because it has become necessary to produce less. The productiveness of labour is diminished each way, and the only person uninjured is the landlord.

To a certain extent, however, the misdirection of industry by government interference is a necessary evil. The duties of government cannot be performed without a public revenue; nor can a considerable public revenue be raised without taxation; and the struggle to escape taxation always tends to divert industry from its natural channels. The tax which is least open to this objection, a tax on rent, must tend to prevent the application of capital to land; a tax on profits to occasion the exportation of capital; a tax on income derived from property to prevent accumulation; a tax on wages to occasion their payment rather in kind than in money, and to prevent the labourer from acquiring durable and visible property in the hope of pleading his poverty as an excuse. Taxes on specific articles are evaded by the substitution of some less burdened or cheaper commodity. The beer and malt duties are avoided by the substitution of spirits. The duties on tea and coffee by the use of roasted corn. Now, every tax, so far as it is evaded, is simply mischievous. A window blocked up to avoid window tax may diminish the light and air enjoyed by a whole family, but adds nothing to the public revenue. A distinct and a still greater injury arises from taxation imposed on the instruments and processes of industry. The salt tax, while it existed, prevented in a great measure the use of salt in agriculture. The duty on advertisements prevents vendors and purchasers from knowing each other's wants and supplies. The duties on leather, on spirits, and on glass, have not only prevented England from attaining, in the manufacture of those commodities, her usual superiority, but have kept her positively behind the improved part of Europe. To prevent fraud on the Excise, the manufacturer is subject to innumerable regulations and prohibitions incompatible with a proper economy of materials and division of labour, and which bend very reluctantly to improvements. To improve is necessarily to alter, and any alteration in the process prescribed by law may entangle the manufacturer within the meshes of a regulating Act of Parliament.

It is commonly supposed that men are sufficiently ready to grumble at taxation; but the fact that they are very imperfectly aware of the degree and kind of evil indirectly inflicted might be proved from many instances. To select only one. Most persons are aware of the far higher price borne by good malting barley above the ordinary barley used only for feeding stock; nor can any one doubt that the price of beer is materially enhanced by this circumstance. But, probably, not one consumer in ten thousand has any idea that this is connected with taxation. Yet, in fact, a large proportion of the barley set aside as unfit for malting would make, as far as nature is concerned, very good malt, but requires a process somewhat different from that which the Excise regulations prescribe, and is consequently rendered by law useless for that purpose. It may easily be conceived that, if the times and mode of ploughing, harrowing, and sowing were prescribed by law, a large portion of land now productive would lie waste.

A Country which has been forced by the folly or the rapacity of its own government, or by the folly or rapacity of other States, to raise a large public revenue, suffers in general far more from the indirect than from the direct effects of taxation; suffers more by being prevented from producing, than by being obliged to pay.

The causes which determine the productiveness of labour in the direct or indirect production ot the commodities used by the labourer appear, therefore, to be four. First, the personal character of the labourer, his corporeal, intellectual, and moral qualities; secondly, the degree in which he is assisted by natural agents; thirdly, the degree in which he is assisted by capital; fourthly, the degree of freedom with which he is allowed to direct his industry.

Proportion of Persons employed in the Production of Commodities for the Use of Labourers to the whole Number of Labouring Families.

If all labourers were employed in the production, direct or indirect, of commodities for their own use, the rate of wages would depend solely on the productiveness of labour. But it is obvious that this could never be the case, unless the labourers themselves were the owners of all the capital and all the natural agents of the country; a state of existence so utterly barbarous as to be without distinction of ranks or division of labour; a state in which a few scattered savage families have sometimes been found, but which exhibits none of the phenomena which it is the business of Political Economy to trace to their causes. A great portion of the labour employed in a civilized community is employed in the production of things in the use of which the labourer is not to participate. In a civilized community, therefore, the extent of the fund for the maintenance of labour depends not only on the productiveness of labour, but also on the number of persons employed in the production of things for the use of labourers, compared with the whole number of labouring families.

It appears to us that there are three purposes to which labour, which might otherwise be employed in supplying the fund for the use of labourers, may be diverted; namely, the production of things, first, to be used by the proprietors of natural agents; secondly, to be used by the government; and thirdly, to be used by capitalists; or, to speak more concisely, though less correctly, labour, instead of being employed in the production of wages, may be employed in the production of rent, taxation, or profit.

Direction of labour.
1. To rent.

First, with respect to rent.

We have already seen that rent depends in part on the productiveness of the natural agent for the assistance of which it is paid. Now any increase in the productive powers of that agent has a tendency to increase rent, and can have none to diminish wages.

The improvements in agricultural skill which have taken place during the last one hundred years have greatly increased the productiveness of the Lowlands of Scotland, and greatly increased the amount of rent; but that increase has been accompanied by an increase, though not in an equal ratio, of the amount of wages. Adam Smith states, that at the time when he wrote (the period of the American War) the usual price of common labour there was 8*d*. a day, or 4*s*. a week. It is now more than 8*s*. a week; a sum capable of purchasing one-third more of raw produce, and three or four times as much of manufactured produce, as the former wages. Though the rental of the Lowlands has more than tripled, though a much larger portion of what the labourer produces is produced for the benefit of the landlord, yet the positive increase of the whole produce more than compensates this apparent inconvenience. Instead of producing, we will say, twenty bushels, of which the landlord received ten, the capitalist two, and the labourer eight, he produces perhaps thirty-five, of which the landlord receives twenty, the capitalist three, and the labourer twelve.

It appears, therefore, that the whole fund for the maintenance of labour is not necessarily diminished in consequence of a considerable portion of the labourers in a Country being employed in producing commodities for the use of the proprietors of the natural agents in that Country. Such labourers may, in fact, be considered as existing only in consequence of the existence of natural agents of extraordinary productiveness. They draw their subsistence not from the common fund, such as it otherwise would be, but from the addition made to that fund by that extraordinary productiveness.

Of course, when we speak of the amount of rent as unimportant to the labourer, we must be understood to mean only that rent which arises from the peculiar or increased productiveness of the natural agent in question, not of that which arises merely from an increase of population. We have already stated that, in the absence of disturbing causes, subsistence may be expected to increase in a greater ratio than population. But, as we then remarked, it certainly is possible, and perhaps, under the influence of superstition and misgovernment, it is probable, that the number of inhabitants in a Country might increase without a commensurate increase of the means, direct or indirect, of obtaining raw produce. Under such circumstances, rents would rise, and labour, which, if the population had remained stationary, would have been employed in the production of commodities for the use of labourers, would now be employed in producing commodities for the use of landlords. A rise of rent so occasioned would of course be detrimental to the mass of the community. It must be recollected, also, that the government of every Country has in some measure the power of deciding in what proportions the different classes of its subjects shall contribute to the public burdens. Some governments have attempted to exempt, as far as they could, the labourers from these burdens, and to throw them as far as they could upon the landlords. Others again have charged, or have allowed individuals to charge, the revenue arising from land with an expenditure for purposes in which the landlords were not solely or principally interested; such as the establishment and maintenance of roads and bridges, the supply of religious, moral, and intellectual instruction, the affording gratuitous medical relief to the sick, and even support to the able-bodied poor or their families. Others, on the other hand, have endeavoured to favour the landlords by imposing public expenditure on the more defenceless portion of the community, the labourers; and many have adopted each of these different lines of conduct on different occasions, or with respect to different portions of their expenditure. The tendency of every such institution must be to augment or diminish the proportion of the labourers employed for the benefit of landlords, compared with that of those who are employed for the benefit of labourers.

Another cause disturbing these proportions is the attempt by a government to create rent, if it can be called rent, by forcibly limiting the bounty of nature. It is possible that, if we had continued to prohibit the corn of Ireland, the incomes of English landlords might have been increased. So, if no coal were allowed to be burned except the produce of a single colliery, the possessor of that colliery would enjoy a princely revenue. But the gain from such a monopoly is not strictly rent; it is oppression and robbery.

2. Direction of labour to supply the consumption of government.

The second purpose to which labour may be diverted from the supply of commodities for the use of labourers is the supply of the consumption of government. It is clear that all the labour that is employed in the support of *unnecessary* establishments, and all the surplus labour which is employed in supporting on an unnecessary scale of expense those establishments which are strictly wanted, is so much taken from the revenue of the whole people. Still more injurious is the employment of labour for the purposes not merely useless, but positively mischievous; in the support of pagodas or bonzes, to keep up or disseminate a demoralizing superstition; in the support of armies and navies to plunder the commerce and ravage the territories of States, which nature enabled to confer mutual benefits, but the folly or wickedness of their rulers force to inflict mutual evil; or in the support of barriers and blockades to maintain the commercial war in which nations are accustomed to spend the breathing time of actual hostility. Unnecessary taxation, even when innocently applied, is fraud or robbery. It is difficult to find a designation for that which is applied to ends still more mischievous than the means; for that which makes plunder and extortion the instruments of still further injury.

It appears at first sight that only this mischievous or useless expenditure ought to be considered as a deduction from wages, since the labour which is employed in effecting the legitimate purposes of government is as much employed for the benefit of the labouring classes as that which is employed in the direct production of commodities for their use. The great object of government is to afford security, and security is of all blessings the most important, and the one least capable of being obtained by uncombined exertions. Those writers who have maintained that whatever is raised by taxation is deducted from the revenue of the Country, seem to have been led to this conclusion, by observing that the object of government is to occasion not positive but negative effects, not to produce good, but to prevent evil. And they have thought it right to deduct what is so spent from the net revenue of the people. But it must be recollected that the mere prevention of evil is one of the principal objects even of individual expenditure. We do not build houses because it is pleasant to breathe the confined atmosphere of a room, but because roofs and walls are the only means by which the inclemency of the seasons can be avoided. We do not buy drugs for our pleasure, but to avert or remove disease. Yet no one ever thought what he spends on medicines and on house rent a deduction from his income. When the members of a Friendly Society raise among themselves a fund for their relief in sickness, they do not consider their contributions a deduction from their wages, but a mode of expenditure. And it may be asked, in what respect does each man's contribution towards the means by which the community is to be protected against internal and external violence and fraud differ from his contribution to a Friendly Society, excepting that those evils are more severe and more constantly imminent than sickness, and less capable of being warded off by individual efforts? It is true that, if the protection could be less expensively obtained, the fund for the maintenance of labour would be increased. But this is merely an exemplification of what we have already stated, that the extent of the fund for the maintenance of labour depends mainly on the productiveness of labour. If fewer fleets, and armies, and magistrates, could preserve the peace, that is, if labour were more productive in affording security, the labouring clases would, *cæteris paribus*, be better off, just as they would be better off if fewer husbandmen or artisans could produce, directly or indirectly, the same quantity of corn; that is, if labour were more productive in supplying food.

But admitting all this to be true, it is also true, as we have already remarked, that the labourer is interested not only in the amount and application of the public revenue, and in the degree in which its payment affects the productiveness of labour, but also in the manner in which the burthen of supplying it is distributed. If the duty on wine were abolished, and an equal revenue raised by substituting an additional duty on coarse tobacco, the labourers, who are the only consumers of coarse tobacco, would purchase, with the same proportion of their wages, less tobacco than before, and the landlords and capitalists, who are the only consumers of wine, would purchase, with the same proportions of their rents and profits, more wine. The productiveness of our labour and the export of our manufactures would be undiminished; even the nature of our exports need not be altered; the only change would be in the returns. More wine and less tobacco would be imported. More labourers, therefore, than before would be employed in obtaining wine for landlords and capitalists, and fewer in obtaining tobacco for labourers.

Nor must it be forgotten that a part of the taxes received by the government of one Country is often paid by the inhabitants of another. We now purchase annually in China about thirty millions of pounds of tea, at about 1*s.* a pound. On the tea so purchased we impose in different ways taxes to the amount of about two hundred per cent. Were we to repeal that taxation, and the price in China were to remain unaltered, our consumption would probably quadruple; but it is highly improbable that we could purchase one hundred and twenty millions of pounds of tea at 1*s.* a pound. The price in China might possibly double; it probably would rise one-half. That rise would have a tendency to raise the rent of land and the wages of labour in the tea-growing districts of China. It must be admitted, therefore, that they are both kept down by the existence of the tax; and that a portion of our duty on tea is, in fact, paid by the inhabitants of the tea-growing districts of China. The same reasoning proves that a part of the English duty on claret is paid by France, and that a part of the duties imposed by foreign nations on some of the commodities which we export, is paid by England. As a portion of the taxes raised by every State is, in fact, paid by the inhabitants of those Countries with which it has commercial relations, and as war and misgovernment are the great causes of taxation, an additional proof is afforded of the degree in which each Country is interested in the freedom and tranquillity of its neighbours.

We have lastly to consider the influence of profits on wages; or, in other words, the extent to which wages may be affected by the employment of labour to produce, instead of wages, things for the use of capitalists. In civilized and well-governed communities, this is the principal purpose to which labour, that otherwise might be employed for the benefit of the labourers, is diverted. The labourers who are employed for the benefit of the owners of natural agents may, as we have seen, be in general considered as a separate class, not withdrawn from the general body, but added to it by the existence of those natural agents. Those who are necessarily employed in effecting the legitimate purposes of government are, in fact, employed for the benefit of the labouring population, and the taxation which supplies their maintenance is not necessarily a deduction from wages, but a mode of expenditure. That few governments have confined themselves to their legitimate office, or employed in effecting that office only the necessary amount of labour, is a melancholy truth; and it is true that the fund for the maintenance of labour may be, and in most Countries has been, and is, more diminished in its amount, and more retarded in its increase, by misgovernment than by all other causes put together. But both misgovernment and that interference of the ruling power between the different classes of its subjects which we have already described as affecting the proportions of rent, profit, and wages to one another, are rather disturbing causes than necessary elements in the calculations of Political Economy; and with these allusions to their influence we shall dismiss them.

Influence of profit on wages.

Rent then being considered as something extrinsic, and taxation a mode of expenditure, the only remaining deduction from wages is profit. And the productiveness of labour being given, the extent of the fund for the maintenance of labour will depend on the proportion which the number of labourers employed in producing things for the use of capitalists bears to that of those employed in producing things for the use of labourers; or, to use a more common expression, on the proportions in which the produce of labour is shared between the capitalist and the labourer.

In a previous portion of this Treatise we defined the word "abstinence" to mean the conduct of him who abstains from the unproductive consumption of any commodity, or who employs labour to produce distant results. In fact, the act of deferring enjoyment. And we explained that labour cannot be efficient unless assisted by, what is the result of abstinence, capital; nor abstinence in itself efficient unless assisted by labour; that each is disagreeable, and must therefore be called into exertion by the prospect of its specific remuneration; abstinence by the hope of profit, and labour by the hope of wages: and we stated, that although in fact the same individual often undergoes both abstinence and labour, yet that we thought it more convenient to consider the capitalist and the labourer as different persons. In the absence of rent, and of unnecessary or unequally distributed taxation, it is between these two classes that all that is produced is divided; and the question now to be considered is, what decides the proportion of the shares?

The facts which decide in what proportions the capitalist and labourer share the common fund appear to be two: first, the general rate of profit in the Country on the advance of capital for a given period; and, secondly, the period which in each particular case has elapsed between the advance of the capital and the receipt of the profit.

General rate of profit.

First, as to the general rate of profit. We have seen that profit is the remuneration of abstinence, and that abstinence is the deferring of enjoyment. The commodity which owes its existence or its preservation to abstinence is capital. Its owner is termed a capitalist, and he is said to *advance* the means by which it is created or preserved. These means are partly materials and implements, (including, under the last term, not merely the ordinary tools of manual labour, but machinery, ships, and even roads, wharfs, and canals,) and partly labour. The materials and implements are supplied by the capitalist directly, the labour is supplied by him indirectly, by advancing the wages of the labourers. The labourers, aided by their implements, convert the materials into a new and vendible commodity, which is termed the *return* of the capitalist. And the capitalist's profit depends on the difference between the value of the advance and the value of the return. In producing the return, the wages and materials are necessarily consumed; they are parted with by the capitalist, and therefore termed circulating capital. The implements are not necessarily consumed; so far as they are unconsumed they remain the property of the capitalist, and are therefore termed fixed capital. The value of that portion of them which remains unconsumed must be added to that of the other returns before the profit can be estimated. The capital of a builder is almost entirely circulating. It consists principally of the bricks, lime, timber, stone, and slate which are the materials with which the house is to be constructed, and of the money necessary to pay the wages of the workmen. His fixed capital (exclusively of his knowledge) consists merely of scaffolding and ladders. All these he advances, and the result, after a certain interval, is a house, together with the former ladders and scaffolding somewhat the worse for wear. The cotton-spinner's advances consist of raw cotton and wages, which are his circulating capital, and buildings and machinery, which are his fixed capital.

General rate of profit.

His returns are a certain quantity of manufactured cotton, and the old buildings and machinery. So a ship-owner's advances consist of his ship, which is his fixed capital, and of its stores, and the wages of his sailors, which are his circulating capital; his returns are his freight, or, in other words, the hire which he receives for the use of his ship, the ship itself, such as it may be, after the voyage, and the stores, if any of them remain unconsumed. The profit in every case consists, as we have already stated, of the difference between the value of the advances and the value of the returns.

How to be estimated.

But in what is this value to be estimated? Of course in something as unsusceptible as possible of variations in its general value. If the value of the advances and returns of the capitalist were estimated in corn or in hops, an abundant season might so reduce the value of either as to make him appear a gainer when in fact a loser. His returns might be worth twenty per cent. more of corn or hops than his advances, and yet be inferior in general value. The commodity least susceptible of variation in its general value, during short periods, is money; and partly from this circumstance, and partly from its general use as a measure of value, it is the medium in which calculations of profit are usually expressed. But, if considerable periods are to be taken, even money is subject to great variations, and any sudden change in the facility of obtaining it, arising from an increased fertility of the mines, or an increased productiveness of labour, or an abuse of banking or paper currency, or from similar causes operating in an opposite direction, may materially raise or depress the general value of money in any one Country, even during short periods.

The best standard of value for philosophical purposes appears to be the command of labour. In the first place, labour, next to money, is the principal subject of exchange. And, in the second place, labour, as the principal instrument of production, as the only instrument that can be employed at will in the creation of whatever is most wanted, varies less in its general value than any other article of exchange. Money, and the necessaries of life which approach nearest to it, derive in part their steadiness of value from their constant power of commanding labour, a power belonging to no other commodity. Estimated indeed in one class of objects, and it is the class most coveted by man, we mean power and pre-eminence, the value of the command of labour is almost invariable. Two persons who, at different times or in different places, can each command the labour of one thousand average labourers, may indeed enjoy in very different degrees the comforts and conveniences of life; but in power and pre-eminence in their respective Countries they must be nearly on a par. Each must be one man in a thousand. Each must be a thousand times richer than the mass of his countrymen. If two shillings in Hindostan will command as many labourers as twenty in England, a Hindoo with £3000 a year is, generally speaking, as great a man in Hindostan as an Englishman with £30,000 a year in England.

Philosophically, therefore, we think that the value of the capitalist's advances and returns ought to be estimated in their command of labour; popularly, their value is estimated in money; and, as the reciprocal values of money and labour seldom vary much between the times of those advances and returns, the popular mode of estimation is seldom incorrect; and we shall therefore use both indifferently.

Causes regulating the rate of profit.

The great difficulty of the subject arises from the circumstance, that the rate of profit is not the subject of contract, but of experiment, and cannot be ascertained even by an individual, except as to his *past* operations. While a transaction is going on, the capitalist may hope that the value of the returns will exceed the value of the advances; he may hope that the excess will be considerable; but he cannot be certain that there will be any excess at all; that there will not be a positive loss. He may say what his profit *has* been, but not what it *is*. Frequently, indeed, he cannot say what it *has* been. A whole series of mercantile or manufacturing transactions may be so linked together that, after having been apparently profitable for years, they may terminate in ruin.

If, however, we could ascertain the value of the returns in all the transactions in this Country which were concluded in the year ending yesterday; and also could ascertain what was the value of the advances, and the average time for which those advances were made before the returns were received, we should know what was the average rate of profit in this Country during the last year. Suppose this point ascertained, and the result to be, that the average rate of profit on an advance of capital for a year was in this Country during the last year ten per cent., the question recurs, what were the causes which determined it to be ten per cent. rather than five per cent. or twenty per cent.?

It appears to us that it must have depended principally on the previous conduct of the capitalists and of the labourers of this Country; on the value of the capital which at some previous period was appropriated by the capitalists to produce commodities for the use of labourers, or, to use a more concise expression, to produce wages; and the number of labourers whom the previous conduct of the labouring population had caused to exist.

Causes regulating the rate of profit.

It will be admitted that, in the absence of disturbing causes, the rate of profit in all employments of capital is equal. If we can ascertain, therefore, what are the causes which regulate the rate of profit in any one of the main employments of capital, we may infer that, in the absence of peculiar disturbance, either the same causes, or, causes of equal force, occasion it to be the same in all others. We will inquire, therefore, into the causes which regulate the rate of profit in one of the main employments of capital,—the advance of wages to the labourers who are themselves employed in producing wages, *using the word wages to signify commodities for the use of the labouring population.*

To simplify the question, we will suppose a small colony settled in a district where there is abundance of fertile land, and protected by situation and character from external and internal violence, so that neither rent nor taxation need be supposed to exist: we will suppose it to be inhabited by ten capitalists and one thousand two hundred labouring families; *that the use of money is unknown;* that all the buildings, the clothes, the furniture, and the food, in fact, the whole consumption of the people, is consumed in one year and reproduced in the next; that each family receives its wages for the year on the first day of the year, and completes its production on the last day, so that all the advances are made on the first day of the year, and all the returns received on the last day; and that, at the time when the situation of the colony was first noticed, each capitalist had in his possession wages for one hundred and twenty families during a year, the produce of the labour of one hundred families during the previous

year, (being his capital, and which, to reduce it to one denomination, we will call one thousand quarters of corn;) and commodities for his own use, which we will call twenty casks of wine, the produce of the labour of twenty families during the previous year; (being the stock reserved for his own consumption.)

Under such circumstances, if each capitalist should employ his capital in setting one hundred families to work to reproduce wages, and twenty more to reproduce commodities for his own use, and the labouring population should neither increase nor diminish, the rate of profit would remain stationary at twenty per cent. per annum. The advances every year would be one thousand quarters of corn, being wages produced by the labour of one hundred families, and commanding the labour of one hundred and twenty; the returns would be a stock of wages commanding the labour of one hundred and twenty families during the next year, which would be, in fact, a reproduction of the previous capital of one thousand quarters, and also a stock of commodities for the capitalist's own use, produced by one-sixth of the labour employed in reproducing the capital, and therefore one-sixth of the value of the capital. The value of the returns on an advance of capital for a year would exceed the value of the advances by one-sixth. The rate of profit therefore would, as we said before, remain stationary at twenty per cent. per annum. And five-sixths of the labourers would be employed in producing commodities for their own use, and one-sixth in producing commodities for the use of the capitalists.

We will now consider the effects of any alteration in the proportion of capital to labour. Suppose that emigration or an unhealthy season should diminish by fifty the number of labouring families: each capitalist would have the same capital; consisting of wages produced by the labour of one hundred families during the year, and which we have called one thousand quarters of corn: but the number of labourers being diminished by one-twenty-fourth, instead of commanding the labour of one hundred and twenty families, they would command the labour of only one hundred and fifteen. The one thousand quarters of corn would be divided among one hundred and fifteen families instead of among one hundred and twenty, and the capitalist would get only fifteen casks of wine during the subsequent year instead of twenty. To take the converse: if immigration or an increase of population should have increased the number of labourers by fifty, each capitalist, instead of one hundred and twenty families, would be able to command the labour of one hundred and twenty-five. The one thousand quarters would be divided among one hundred and twenty-five families, instead of among one hundred and twenty, and the capitalist might employ twenty-five families to produce wine for himself instead of twenty. In the one case, profits rise from twenty to about twenty-five per cent.; in the other, they fall to about fifteen. On the other hand, if we suppose the labouring population to remain stationary at one thousand two hundred families, but the capitalists, instead of employing each one hundred families in the production of wages, and twenty in the production of profits, to employ each one hundred and five in the production of wages, each capitalist would at the end of the year have a capital of one thousand and fifty quarters produced by the labour of one hundred and five families, and commanding the labour of one hundred and twenty; or if they each employed in the production of wages only ninety-five families, and in the production of profits twenty-five, each would have at the end of the year a capital of nine hundred and fifty quarters, produced by the labour of ninety-five families, and commanding the labour of one hundred and twenty. Profits would fall in the first instance from twenty per cent. to less than fifteen; in the second, they would rise to more than twenty-five. If, however, the increase of the number of labourers employed in the production of wages should be accompanied by a proportionate increase in the whole number of labourers; or if, when the number of labourers employed in the production of wages was diminished, the whole number of labourers should be diminished in proportion; or, in other words, if the proportion of capital to labour remained unaltered, the rate of profit would be also unaltered. If each were increased, or each diminished, but in different proportions, profits would rise or fall according to the relative variations in the supply of wages and labour.

It appears, therefore, that, under the most simple state of circumstances, the rate of profits depends, as we said before, on the previous conduct of the capitalists and the labourers in a Country.

In this hypothesis we have supposed all the capitalists to act together. And as every permanent increase of capital while the number of labourers remained the same would, under the supposed circumstances, occasion a proportionate diminution of the rate of profit, it never could be the interest of the capitalists, as a body, to increase their capital, except with a view to increase the number of labourers; or even to keep up their capital, except so far as it should be necessary to keep up the existing number of labourers. It would be their interest, if the population were incapable of increase, to devote to the production of wages labour just sufficient to produce the necessaries of life for that stationary population, if the population were advancing just sufficient to enable it to advance; to treat the labourers, in short, as a farmer treats his horses, or a slave-owner his slaves.

Under such circumstances, supposing the capitalists to be governed solely by their interest, the rate of profit would depend partly on the productiveness of labour, and partly on the period that must elapse between the time of the advances and of the returns. Given the period of advance, it would depend on the productiveness of labour. If a labourer by a year's labour could produce a return which, to reduce it to one denomination, we will call ten quarters of corn, and five quarters were enough for his support, the rate of profit would be one hundred per cent. per annum. By an advance of five quarters the capitalist would obtain a return of ten. If the labourer could produce fifteen, the rate of profit would be two hundred per cent.; by an advance of five the capitalist would obtain fifteen. If the labourer could produce only seven and a half, profits would be fifty per cent. On the other hand, the productiveness of labour being given, the rate of profit would depend on the period for which the capital must be advanced. When the labourer receiving five quarters as wages could, by a year's labour, produce ten, a capitalist with a capital consisting of ten quarters could employ two labourers, each of whom would return to him ten quarters every year. But if, instead of returning ten quarters at the end of one year, a labourer returned twenty quarters at the end of two years, a capitalist with a capital of ten quarters would be able to employ only one labourer instead of two; for if he were to employ two his capital would be exhausted before it was reproduced. Only one-half of the number of labourers could be employed by the same amount of capital, and instead of getting a net revenue of ten quarters every year, the capitalist would get a net revenue of only ten quarters every two years.

Happily, however, the capitalists of a Country do not act as a body. Each pursues his own scheme of aggrandizement, indifferent to its effect on his neighbours, and it is chiefly to their mutual competition that we owe the increase both of capital and of population. To revert to our original hypothesis; suppose one of the capitalists, instead of employing, like each of the others, twenty labourers to produce commodities for his own use and one hundred to produce wages, to employ one hundred and ten labourers in the production of wages. At the end of the year he would have a capital consisting of one thousand one hundred quarters of corn produced by the labour of one hundred and ten families, and commanding, *at the existing rate of wages*, the labour of one hundred and thirty-two families; and the nine others would have each a capital consisting of one thousand quarters, produced by the labour of one hundred families, and commanding, *at the existing rate of wages*, one hundred and twenty families. The whole capital of the Country, instead of its former amount, namely, ten thousand quarters, being wages for one thousand two hundred families, would amount to ten thousand one hundred quarters, being wages for one thousand two hundred and twelve families. But as there would be only one thousand two hundred families to receive them, profits would fall about one per cent., or from twenty per cent. to a fraction less than nineteen per cent. per annum. This fall of profits would prevent the capitalist to whose conduct it was owing from reaping the full benefit of his accumulation. He would find himself possessed of a capital consisting of one thousand one hundred quarters, being wages produced by the labour of one hundred and ten families, and commanding the labour of one hundred and thirty and a fraction; but every other capitalist would find his capital of one thousand quarters, produced by the labour of one hundred families, commanding the labour of a small fraction less than one hundred and nineteen families. The first, or accumulating capitalist, would find the value of his capital and the amount of his profits increased, though the rate of profits had fallen one per cent. But all the other capitalists would find both the value of their capital and the amount of their profits diminished.

Now there is nothing to which a capitalist submits so reluctantly as the diminution of the value of his capital. He is dissatisfied if it even remain stationary. Capitals are generally formed from small beginnings by acts of accumulation, which become in time habitual. The capitalist soon regards the increase of his capital as the great business of his life; and considers the greater part of his profit more as a means to that end than as a subject of enjoyment. It is probable, therefore, that the other capitalists in the Country would endeavour to keep the value of their capitals unimpaired, though at the expense of a diminution of the general rate of profit. One after another would follow the example of the first-mentioned capitalist, and devote to the increase of their respective capitals a portion of the labour previously employed in furnishing commodities for their own use. In time each capitalist, instead of employing one hundred families in the reproduction of capital, and twenty in supplying his own enjoyments, would employ one hundred and ten in the reproduction of capital, and only ten for his own purposes. The rate of profit would fall from twenty to ten per cent., and, of the one thousand two hundred labouring families, one thousand one hundred would be employed in producing wages, and only one hundred in producing profits. The annual produce of the Country, instead of ten thousand quarters of corn and two hundred casks of wine, would consist of ten thousand one hundred quarters of corn and one hundred casks of wine. Instead of five-sixths of the labourers in the Country being employed in producing commodities for the use of the labourers, and one-sixth for the use of capitalists, eleven-twelfths would be employed for the benefit of the labourers, and only one-twelfth for the benefit of the capitalists.

This fall of profit, however, could take place only on the supposition of the number of labouring families remaining unaltered. But it is highly improbable that it could remain unincreased. The increase of wages would enable the labourers to marry earlier, or to raise more numerous families. If labour should remain equally porductive, their numbers might increase until the former proportion of labourers to capital had been restored. All the results would be beneficial. The labourers would not be worse off than before the additional accumulation took place, and the capitalists would be better off. The value of their capitals and the amount of their profits would be increased, and the rate of profit would be again twenty per cent. per annum.

We set out with supposing a Country possessing an abundance of fertile land. Under such circumstances the productiveness of labour might for a long period continue, or even increase, with every addition to the number of its inhabitants. But in a densely-peopled Country the powers of labour seldom remain the same during an increase of population. In manufactures labour becomes proportionably more productive. In agriculture, unless aided by increased industry or skill, or by permanent improvements of the soil, it becomes proportionably less so. And, as the labourer consumes chiefly raw or slightly-manufactured produce, the increased facility of obtaining manufactures may not make up for an increased difficulty in obtaining raw produce. In an old Country, therefore, when the rate of profit has been reduced by an increase of capital, it seldom can be fully restored by a proportionate increase of population, unless either the labourer receives a smaller quantity of raw produce than before, or the necessity of cultivating lands of inferior productiveness is obviated either by permanent improvements, such as draining marshes or fertilizing bogs, or by additional industry or skill, or by the importation of raw produce. In such Countries the natural progress seems to be an increase of capital, occasioning a fall of the rate of profit; a check to that fall, occasioned by an increase of the labouring population; a check to that increase, occasioned by an increased difficulty in obtaining raw produce; and a diminution, rarely amounting to a removal, of that difficulty, occasioned by permanent agricultural improvements, increased industry or skill, or foreign importation; leaving, as the general result, a constant tendency towards an increase of capital and population, and towards a fall in the rate of profits.

In our hypothesis we have supposed the whole capital of the Country to be consumed and reproduced every year. Under such circumstances it has appeared that, the number of labourers remaining the same, no permanent addition could be made to capital without occasioning immediately a proportionate diminution of the rate of profit, since that addition would disappear in a year unless reproduced by a repetition of the sacrifice on the part of the capitalist by whom it was originally created. But the result would be different if that addition were made in a form requiring no further labour for its reproduction. Suppose the capitalist, instead of adding five to the hundred families employed in producing wages, were to employ the additional five in the construction of a durable machine enabling one man to do some piece of work that previously required two. At the end of the first year each capitalist would possess wages for one hundred and twenty families, produced by the labour of one hundred families; commodities for his own use, produced by the labour of fifteen families; and his machine, produced by the labour of five families. But in every subsequent year he might obtain wages for one hundred and twenty families by employing only ninety-nine families and his machine, and might employ twenty-one families in producing commodities for himself. Both the rate and the amount of profit would be increased without any diminution of wages. Such a machine is a new labourer added to the existing number of labourers, but a new labourer whom it costs nothing to maintain. It adds to the amount of the profit of the capitalist who has constructed it, without either taking from the profits of other capitalists, as must be the case when additional capital is created, which must be kept up and worked by additional labour; or taking from the wages of the other labourers, as must be the case when an additional labourer is added, whose subsistence must be taken from the common fund. A machine or implement is, in fact, merely a means by which the productiveness of labour is increased. The millions which have been expended in this Country in making roads, bridges, and ports, have had no tendency to reduce either the rate of profit or the amount of wages. They have, in fact, had a tendency to keep up both, by enabling labour to be more productive, and consequently enabling the circulating capital and the population of the Country to increase in corresponding ratios.

It appears, therefore, that in one of the main employments of capital, namely, the employment of labourers to produce commodities for the use of labourers, or, in other words, to produce wages, the difference between the value of the returns and the value of the advances depends on the amount of labour which at a previous period was devoted to the production of wages, compared with the amount of labour which those wages when produced can command. And as the rate of profits in every different employment of capital has a tendency to equality, we may infer that all capitals, however employed, yield about the same rate of profit as those which are employed in the production of wages.

Average period of advance of capital.

The first of the two principles which regulate the division of the produce between the capitalist and the labourer, namely, the rate of profit in the advance of capital for a given time, having been, in some measure, ascertained, we proceed to inquire into the causes which regulate the second principle, namely, the average time for which the capital must be advanced.

It must be recollected, however, that the expression "the capitalist's share," though familiarly used by Economists, is not strictly correct. When the product is completed, it is the sole property of the capitalist, who has purchased it by paying in advance the labourer's wages. What is meant, therefore, by "the capitalist's share," is that portion of the product, or of the price for which it sells, which the capitalist can retain and apply for his own purposes, keeping the value of his capital unimpaired. What is meant by "the labourer's share" is that portion of the produce, or of the price for which it sells, which the capitalist, if he keep his capital unimpaired, cannot employ for his own purposes, but must employ in advancing the price of the labour by which the work of reproduction is to be performed. We have already shown that, the period of advance being given, these proportions are determined by the rate of profit. It is equally clear that, the rate of profit being given, they must be determined by the period of advance. If a capitalist has a return which we will call twelve quarters of corn, and we wish to know how much of it he must retain as capital, and how much he may use as profit, the first inquiry is, for what period must he advance his capital before he can again obtain a similar return? The next inquiry is, what is the current rate of profit? If the answer to the first inquiry be, one year, and to the second, twenty per cent. per annum, it follows that, by constantly employing ten quarters as wages, he will receive two as profit. If the period of advance be only six months, the rate of profit continuing at twenty per cent. per annum, he must employ eleven and a fraction as capital, and will not receive quite one as profit. If the period of advance be two years, the rate of profit continuing at twenty per cent. per annum, rather less than eight quarters will form a sufficient capital, and rather more than four will be profit. With every prolongation of the period of advance, the rate of profit continuing the same, the capitalist's share must increase. With every abridgement of that period it must diminish. And it is equally obvious that, the period of advance being given, the capitalist's share must augment with every increase of the rate of profit, and diminish as that rate decreases.

Time of advance of capital.

On what then does the period for which capital is to be advanced depend? To this question no general answer can be given. The period differs according to the accidents of soil and climate; it varies indefinitely in every different business, and even in employments which, in other respects, are perfectly similar.

In Europe the harvest is annual; in Hindostan it recurs every six months. The average period for which agricultural wages are advanced must be at least twice as long in Europe as in Hindostan. A great part of the capital employed in breeding horses must be advanced four or five years; that employed in planting must be advanced forty or fifty. A very small part of the capital of a butcher or a baker is advanced for more than a week. The stock of a fishmonger spoils in a day; that of a Rhenish wine-merchant is improved by being kept a century. As a general rule, the average period is longer or shorter in one Country than in another in an inverse proportion to the general rate of profit. In the general market of the world, a Country in which the rate of profit is low has over one where it is high an advantage which increases at compound interest, as the period of advance is prolonged. The rate of profit in Russia is supposed to be above twice as high as in England. We will suppose that rate to be five per cent. per annum in England, and ten in Russia. A commo-

Wages and profit. Time of advance of capital.

dity produced in Russia by an advance of £10 for twenty years would sell for nearly £70. A commodity produced in England by the advance of £20 for the same time would sell for less than £60. The difference in the rate of profit would far outbalance a doubling of the first expenditure. Profits[*] are supposed to be lower in Holland and in England than in any other part of the globe. The English and the Dutch, therefore, have almost a monopoly in those trades in which the returns are distant. Abstinence with them is a cheap instrument of production, and they use it to the utmost. In their commerce with other nations they generally pay in ready money, but give a very long credit. They purchase raw produce, and sell manufactures. In many instances they even advance to the foreign Countries the first expenses of production. The indigo of Bengal, the wines of the Cape, the wool of Australia, and the silver of Mexico, are in a great measure produced by the advance of English capital. The accumulated interest on such advances would be an intolerable addition to the value of the returns if the rate of profit were high. This circumstance occasions a tendency to uniformity in the proportion, in different Countries, in which the produce is shared between the capitalist and the labourer. Where profits are high the capitalist's share is kept down by the shortness of the period for which his capital is advanced. Where they are low it is kept up by the prolongation of that period.

The labourer is far more interested in the comparative rate of profit than in the comparative period for which capital is advanced. The productiveness of labour and the period of advance being given, we have seen that the amount of his share of the product depends on the rate of profit. It is his interest, therefore, in the first place, that when capital is employed *in the production of the commodities which he consumes*, all other things remaining the same, the rate of profit should be low. And if it were possible that the rate of profit in other employments could be higher, capital would be diverted from the only production in which the labourer is directly interested—the production of commodities for his own use—and the general fund for the maintenance of labour would be diminished. All other things, therefore, remaining the same, it is the labourer's interest that the rate of profit should be *universally low*. But it must be recollected, first, that the average period for which capital is advanced, especially in the production of the commodities used by labourers, is so short that the capitalist's share is small even when profits are high: if the advance has been for six months, the capitalist's share, at the high rate of twenty per cent. per annum, would be less than one-eleventh: and, secondly, that a high rate of profit is generally found to accompany a great productiveness of labour. And therefore that, in general, the labourer is better paid, or, in other words, receives a larger amount of commodities, when profits are high, that is when he receives a small share, than when profits are low, that is when he receives a large share, of the value of what he produces. The increase of the labourer's share from ten-elevenths to twenty-one-twenty-seconds, which would be the consequence in the case which we have supposed of a fall of profits by one-half, would add very little to the *amount* of his wages.

On the other hand it is his interest that, when capital is employed in the production of *what he himself consumes*, the period of advance should be short. We will suppose a labourer employed on the least productive soil to produce by a year's labour employed in hoeing and weeding an additional produce of twenty-two quarters of corn; the wages of labour to be £20 a year; the rate of profit to be ten per cent. per annum, and a year to elapse between the advance of the wages and the corn being fit for use; the price of the corn would be £22; the labourer would receive twenty quarters, or, what is the same, £20, with which he could purchase twenty quarters. But if corn were not fit for use until it had been kept for ten years, on the same data, the corn, instead of selling for £22, would sell for above £50; the labourer would receive less than ten quarters instead of twenty, or, what comes to the same, his wages, instead of twenty, would purchase less than ten quarters. To produce the corn would require the same degree of labour as before, but ten times as much abstinence

Another consequence of the prolongation of the period of advance would be, that with the same amount of capital the capitalist would be able to maintain much fewer labourers than before. If ten quarters were necessary to maintain a labouring family during a year, and they could reproduce eleven in a state fit for consumption at the end of the year, a capital of one hundred quarters would enable a capitalist to keep in constant employ ten labouring families during the first year, and eleven during every subsequent year. But, if the corn were not fit for consumption till the end of ten years, a capitalist starting with a capital of one hundred quarters could not maintain more than a single family, For, if he were to maintain more, the capital would be exhausted before it was reproduced. The prolongation of the period of advance would have precisely the same effect as a diminished productiveness of labour.

But the prolongation of the period of advance of the capital employed in the production of the commodities which the labourer does not consume is utterly indifferent to him. If a labourer by a year's labour can produce twenty-two ounces of lace, his wages being £20 a year, and advanced for a year, and the rate of profit being ten per cent., he will receive ten elevenths of the value of the lace, or, in other words, he might purchase with his wages twenty ounces of lace. If the lace required keeping for ten years, his wages would purchase less than ten ounces of the lace in its complete state. But as he never wishes to purchase lace, and as the prolongation of the period for which capital must be advanced in the production of lace would not affect either the productiveness of labour, or the rate of profit, or the period of advance in any other employment, it would be utterly indifferent to him; it would affect only the consumers of lace.

Profit.

We have seen that, although practically high wages and high profits generally go together, yet, all other things remaining the same, it is the interest of the labourers that profits should be universally low. It is equally clear that it is the interest of the capitalists that they should be universally high. A fall in the rate of profit in any one employment has a tendency to force capital into the others. This diminishes the competition among the first-mentioned capitalists, but increases it among the others. The first are relieved, but it is only by the loss being spread over the whole body.

But a prolongation of the period of advance affects the capitalist only so far as he uses the specific commodity with respect to which that prolongation has taken place. The rate of profit on the advance of capital for a given period being given, the length of the period between the bottling of a pipe of port and its being fit for use affects a wine merchant only so far as he drinks port. As a consumer, it is his interest that the period should be short; as a capitalist it is immaterial to him.

We have now given an outline of the causes which affect the general rate of wages, the most important and the most difficult of all the subjects embraced by Political Economy. It has appeared, first, that the general rate of wages depends on the amount of the fund for the maintenance of labourers, compared with the number of labourers to be maintained.

Secondly, that the amount of that fund depends partly on the productiveness of labour in the production of the commodities used by the labourer, or, to speak more concisely, in the production of wages, and partly on the number of labourers employed in the production of wages compared with the whole number of labourers.

Thirdly, that the productiveness of labour depends on the character of the labourer, or the assistance he derives from natural agents, and from capital, and on his freedom from interference.

Fourthly, that, in the absence of rent and improper or unequally-distributed taxation, the proportion of the labourers employed in producing wages to the whole number of labourers depends partly on the rate of profit, and partly on the time for which the capital employed in the production of wages must be advanced.

Fifthly, that the rate of profit, at any given time, depends on the previous conduct of capitalists and labourers.

And, sixthly, that the period for which capital must be advanced is subject to no general rule, but has a tendency to be prolonged when profits are low, and shortened when they are high.

The inquiry into the causes which regulate wages has, in a great measure, ascertained those which affect profits. We have to add only that profits may be considered in three points of view: first, as to their rate; secondly, as to their amount; and, thirdly, as to the amount of desirable objects which a given amount of profit will command. The causes which decide the rate of profit have been already considered. It has been shown that they depend on the proportion which the supply of capital employed in providing wages bears to the supply of labour. The rate being given, the amount of the profit received by any given capitalist must depend, of course, on the amount of his capital. It follows that, when the rate of profit falls in consequence of an increase of capital without a proportionate increase of labourers, the situation of the existing capitalists, as a body, cannot be deteriorated, unless the fall in the rate has been so great as to overbalance the increase of the amount. Two millions, at five per cent., would give as large an amount of profit as one million at ten. At seven and a half per cent. they would give a much larger. And such is the tendency of an increase of capital to produce, not indeed a corresponding, but still a positive increase of population, that we believe there is no instance on record of the whole amount of profits having diminished with an increase of the whole amount of capital.

Totally distinct from the amount of profit is the amount of desirable objects which a given amount of profit will purchase. A Chinese and an English capitalist, each of whose annual profit will command the labour of ten families for a year, will enjoy in different degrees the comforts and conveniences of life. The Englishman will have more woollen goods and hardware, the Chinese more tea and silk. The difference depends on the different productiveness of labour in China and in England in the production of those commodities which are used by the capitalists in each Country. In the command of labour, and in the rank in society which that command gives, they are on a par. We have seen that, as population advances, labour has a tendency to become less efficient in the production of raw produce, and more productive in manufactures. The same amount of profit, therefore, will enable the capitalist in a thinly-peopled Country to enjoy coarse profusion, or among a dense population moderate refinement. A South American, with an annual income commanding the labour of one hundred families, would live in a log-house on the skirts of a forest, and keep, perhaps, one hundred horses. An Englishman with the same command of labour would live in a well-furnished villa, and keep a chariot and pair. Each would possess sources of enjoyment totally beyond the reach of the other.

Variations of the Amount of Wages and the Rate of Profits in different Employments of Labour and Capital.

In the previous discussion we have assumed the existence of a certain average rate of wages and average rate of profits. We now propose to consider the influence of some specific causes on the amount of wages and the rate of profits in different employments of labour and capital.

The justly-celebrated chapter on this subject in the *Wealth of Nations* begins with the following words:

"The five following are the principal circumstances which, so far as I have been able to observe, make up for a small pecuniary gain in some employments, and counterbalance a great one in others. 1. The agreeableness or disagreeableness of the employments themselves. 2. The easiness and cheapness, or the difficulty and expense, of learning them. 3. The constancy or inconstancy of employment in them. 4. The small or great trust which must be reposed in those who exercise them. 5. The probability or improbability of success in them." Book i. ch. x.

As our remarks will be chiefly a commentary on those of Adam Smith, we shall, as far as we can, follow his arrangement. We shall begin, therefore, by the influence of agreeableness or disagreeableness.

1. Agreeableness.

The act of labouring implies a sacrifice of ease, and it is chiefly to this sacrifice that our attention is directed when we speak of wages as the remuneration for labour. But, as we have already observed, the indolence which generally indisposes to severe or long-continued bodily exertion is not in all cases the only feeling which the labourer has to conquer. His employment may be dangerous, or physically disagreeable, or degrading. In any one of these cases his wages are the reward not only of the fatigue, but of the hazard, the discomfort, or the discredit which he has encountered. Adam Smith, however, has remarked, that the prospect of hazards from which we can hope to extricate ourselves by courage and address is not disagreeable, and does not raise the wages of labour in any employment. "The dangers and hair-breadth escapes of a life of adventure, instead of disheartening young people, seem frequently to recommend a trade to them. But it is otherwise," he observes, "with those in which courage and address can be of no avail. In trades which are known to be very unwholesome the wages of labour are always remarkably high."[*]

Unwholesomeness, indeed, is generally united to other disagreeable circumstances. Dirt, dust, deleterious atmosphere, exposure to continued heat or cold, or to sudden transitions from the one to the other, which are the principal causes of unhealthiness in any business, are also the principal causes of its being generally disagreeable. When toil, disease, and discomfort, are all to be encountered, the temptation must indeed be high. But this union is not universal. The trade of a house-painter is one of the most agreeable, and one of the most unwholesome, among ordinary occupations. On the other hand, that of a butcher, though brutal and disgusting, is eminently healthy. The wages of each are, we believe, about equal, and considerably exceed the remuneration for the mere labour undergone, which, in fact, is in both cases very trifling. But the fear of popular odium, and, what is always strongest amongst the least educated, the fear of popular ridicule, as they are amongst the most powerful feelings of our nature, are the most effectual means by which the wages of an employment can be increased. To Adam Smith's instance of a public executioner may be added that of a common informer; both of whom are remunerated at a rate quite disproportioned to the quantity of work which they do. They are paid not so much for encountering toil as for being pelted and hissed. The most degrading of all common trades, perhaps, is that of a beggar; but, when pursued as a trade, it is believed to be a very gainful one.

Such appears to be the influence upon wages of danger, discomfort, and disgrace. And it may be supposed that any peculiarly agreeable employment is generally as comparatively underpaid as peculiarly disagreeable ones are overpaid. Adam Smith has accordingly remarked that in a civilized society hunters and fishers, who follow as a trade what other people pursue as a pastime, are generally very poor people. "Fishermen," he observes, "have been poor from the times of Theocritus. The natural taste for these employments makes more people follow them than can live comfortably by them; and the produce of their labour, in proportion to its quantity, comes always too cheap to market to afford any thing but the most scanty subsistence to the labourers." Hunting, however, can scarcely be said to exist as a trade in any well-civilized Country. And we doubt the accuracy of Adam Smith's statement as to fishermen; unless, as perhaps was the case, he intended to confine them to the small number of anglers and poachers on rivers, who do, in fact, follow as a trade what other men enjoy as a pastime. Marine fishery is a business of too much toil and hardship to be very attractive; and if any proof, besides the well-fed persons and ample clothing of the men and their families were required, of its being well paid, it would be found in the fact that the capital employed in it, which is far from inconsiderable, generally belongs to the fishermen themselves.

As a general rule, we fear it must be admitted that the occupations open to those who are not possessed of capital differ only in the degree in which they are disagreeable. The least disagreeable are man's primeval occupations, those of a shepherd and a tiller of the ground. And, accordingly, we believe that in every state of society the lowest wages are those which are paid to agricultural labourers. The current wages of common agricultural labourers may, therefore, in general be considered as representing the value, at the time and place where they are paid, of mere bodily labour. If, at the same time and place, we find the services of any other labourer more highly paid, we may infer either that his employment is subject to some peculiar disadvantage, or that, in fact, rent or profit enter into his remuneration.

Adam Smith states that, in point of agreeableness or disagreeableness, there is little or no difference in the greater part of the different employments of stock, though a great deal in those of labour; and he infers, as we have seen, that average profits are more nearly on a level than average wages. That portion of profit which is simply the remuneration for abstinence is certainly, at the same time and place, nearly on a level; for abstinence, being a negative idea, does not admit of degrees, excepting in the amount of capital from the unproductive use of which the capitalist abstains, and the length of time during which he abstains.

But we cannot admit that the agreeableness or disagreeableness of the greater part of the different employments of capital is about the same. Nor would Adam Smith have stated them to be so unless he had used wages in a wider, and profit in a narrower sense than that which has been adopted in this Treatise. Wages, in the sense in which we have used the word, are paid almost exclusively for undergoing bodily labour or bodily inconvenience, and bodily labour is almost always disagreeable. But the labour of employing capital is principally mental, and mental exertion is often delightful. We frequently hear of men who are devoted to their profession or their business, however generally unattractive. A surgeon once told us that, whatever were his income, his utmost happiness would be to superintend a great military hospital. Half the miseries of mankind have arisen from the delight of statesmen in governing, and of generals in war. Again, the mere labourer receives mere pecuniary wages, or food, shelter, and clothing, of equal value. The capitalist is often paid by power or reputation, and sometimes receives the highest of human rewards, the consciousness that he has been widely and permanently useful. And, on the other hand, there are employments, as for instance the slave-trade, which imply fatigue, hardship, and danger, public execration, and, if a slave-trader can be supposed to reflect on the nature of his occupation, self-reproach. It is unnecessary to prove by a formal induction that, when almost all that renders life agreeable, or even endurable, is sacrificed to profit, the profit must be great; or that competition must reduce very low the pecuniary reward or valuable remuneration of occupations which seem to carry with them their own reward.

It may not appear obvious why the extra profit of a disagreeable employment should bear any proportion to the value of the capital employed in it. It must be remembered that, since the number of persons possessed of a given capital becomes rapidly smaller as the amount of the supposed capital is larger, the possessors of any given amount of capital enjoy a sort of monopoly, which becomes stricter and stricter as the given amount is larger; and, secondly, that the larger a man's capital, and consequently his income, the greater must be the temptation necessary to induce him to encounter moral or physical evil in the hope of increasing it. On the other hand, both the trouble and the inferiority of rank that accompany any trade are generally in inverse proportion to the capital employed. Where, indeed, the objection to a trade arises from its moral turpitude, as in the case of the keeper of a gambling-house, or of any place of still more shameful resort, its extent will only increase its infamy But in the absence of this peculiar objection, the same trade which on a small scale is mean, is respectable in a large way, and almost dignified when carried to its greatest extent. The trouble cannot be so completely got rid of, but when the capital is large enough to enable the employment of clerks and junior partners of great knowledge and high character, it may often be so far reduced as to occupy a small portion of the principal's daily time. There are at this instant many persons busily engaged, and even distinguished in politics and literature, who are also at the head of great banking, brewing, or mercantile establishments. It is not probable that their occupations in business can employ much of their time.

---

[*] Book i. ch. x.

The result that might be anticipated from these opposing circumstances is, that that part of profit which is the remuneration for the trouble and other sacrifices, independent of abstinence made by the capitalist, though it must positively increase in amount, yet generally bears a smaller proportion to the capital employed as that capital increases in value. And this anticipation is, we think, confirmed by observation. There are, we apprehend, few persons employing in England a capital of £100,000, who would not be satisfied with a profit of less than ten per cent. per annum. A manufacturer of considerable eminence, with a capital of £40,000, complained to us of the smallness of his profits, which he estimated at twelve and a half per cent. About fifteen per cent. we believe to be the average that is expected by men with mercantile capitals between £10,000 and £20,000. Scarcely any wholesale trade can be carried on with a capital of less than £10,000. The capitals of less value, therefore, generally belong to farmers, shopkeepers, and small manufacturers, who, even when their capital amounts to £5000 or £6000, expect twenty per cent., and when it is lower a much larger per centage. We have heard that stall fruit-sellers calculate their gains at 2*d.* in the shilling, or twenty per cent. per day, or something more than 7000 per cent. per annum. This seems, however, almost too low. The capital employed at any one time seldom exceeds in value 5*s.*, twenty per cent. on which would only be 1*s.* a day; a sum which would scarcely pay the wages of the mere labour employed. It is, however, possible that the capital may sometimes be turned more than once in a day; and the capitalists in question, if they can be called so, are generally the old and infirm, whose labour is of little value. The calculation, therefore, may probably be correct, and we have mentioned it as the highest apparent rate of profit that we know.

2. Facility of learning the business.

"Secondly," says Adam Smith, "the wages of labour vary with the easiness and cheapness, or the difficulty and expense, of learning the business.

"When any expensive machine is erected, the extraordinary work to be performed by it before it is worn out, it must be expected, will replace the capital laid out on it with at least the ordinary profits. A man educated at the expense of much labour and time may be compared to one of these expensive machines. The work which he learns to perform, it must be expected, over and above the usual wages of common labour, will replace to him the whole expense of his education with at least the ordinary profits of an equally valuable capital. It must do this in a reasonable time, regard being had to the very uncertain duration of human life, in the same manner as to the more certain duration of the machine. The difference between the wages of skilled labour and those of common labour is founded on this principle." Book i. ch. x.

We agree with the whole of this admirable passage, except that we think it shows the propriety of rather terming the surplus remuneration of skilled over common labour profit than wages. It is an advantage derived by the skilled labourer in consequence partly of his own previous conduct, and partly of that of his parents or friends;—of the labour and of the expense which they respectively contributed to his education. It is profit on a capital, though on that sort of capital which cannot be made available without the labour of its possessor.

Adam Smith has remarked that, in the liberal professions, this labour and expense are very inadequately remunerated; and he attributes the slightness of their remuneration first to the desire of the reputation which attends upon superior excellence in any of them; secondly, to the natural confidence which every man has, more or less, not only in his own abilities, but in his own good fortune; and thirdly, as far as literature and the church are concerned, to the number of persons who are educated for those occupations at the public expense.

The two first causes operate very forcibly. The influence of the third he has, we think, exaggerated, or, perhaps, its force may have much diminished since he wrote. In the first place, though our population has nearly doubled in the interval, the number of provisions for affording gratuitously the means of a liberal education has not materially increased. And, secondly, from the change which has taken place in the style of living at the places of education, and in many cases from the nominal value of the provisions having remained unaltered, while money has lost more than half its value, these provisions now afford much less real assistance to the persons who obtain them. Adam Smith seems to have supposed that the greater part of the clergy were educated at the expense of the public, and he expressly states that few were educated altogether at their own. But at present there are scarcely any undergraduates at either of our Universities wholly maintained by a foundation: probably there are not twenty who receive from such a source one-half of their expenditure, and by far the greater number receive no pecuniary assistance except from the relative cheapness of instruction. We say *relative* cheapness, because the sum of money positively paid for instruction is perhaps as great at Oxford and Cambridge as at most other Universities; but the attention bestowed by the teacher on each individual student is considerably greater. In the foreign Universities a lecture is a discourse delivered by the professor; in ours, the College lectures, which are the principal means of instruction, are, in a great degree, examinations undergone by the pupils. There can be no comparison between the labour imposed on the teacher in these two modes of education. But that which is the laborious one necessarily confines each tutor to a small number of pupils. If our foundations did not afford them an income, our tutors must either require a much larger remuneration from each pupil, or adopt the

Distribution. Inequalities of wages and profit in different employments.

foreign mode of teaching by discourses delivered to large assemblies.

The principal cause which fills the avenues to some of the liberal professions with candidates so numerous as materially to diminish one another's reward is one which Adam Smith has omitted.

The average expense of providing in the cheapest manner for the maintenance of a child until it can maintain itself by ordinary labour may perhaps amount to about £40. This is double the sum for which a parish will indemnify the father of a bastard. The parish, however, speculates on the chances of the child's death. The average expense of giving to a gentleman's son the education which is essential to his holding his father's rank cannot be estimated at less than £2,040. But neither the labour which the boy undergoes, nor the expense borne by his father, is incurred principally in order to obtain future profit. The boy works under the stimulus of immediate praise or immediate punishment. It never occurs to the father that it would be cheaper to have his child nursed in the country at 2*s*. a week till he is eight years old, and then removed to a farm-yard or a cotton-mill; and that in giving him a more expensive education he is engaging in a speculation which is likely to be unprofitable. To witness a son's daily improvement is, with all well-disposed men, or rather with all men, except a few outcasts, one of the greatest sources of immediate gratification The expense incurred for that purpose is as much repaid by immediate enjoyment as that which is incurred to obtain the most transitory pleasures. It is true that a further object may also be obtained, but the immediate motive is ample.

But the extra expense and labour thus incurred in some cases constitute the whole expense and labour of preparation for a liberal profession, and in all cases constitute the bulk of that expense and labour. In the church they constitute the whole of the expense, and almost all the labour. A graduate of Oxford or Cambridge may have a very little more to read before he takes orders, but has absolutely nothing more to pay. What he obtains, therefore, as a clergyman, after deducting the mere wages of his additional labour, is pure gain. And when we consider how many are the motives for undergoing that labour, besides the merely pecuniary ones, we might be tempted to wonder that the pecuniary rewards should remain so high. Three circumstances keep them up: two by diminishing the number of candidates, and the third by raising the fund applicable to their use. The two former ones are the indelibility of the clerical character, and the interdiction of clergymen from almost all secular employments, especially from those which offer the most glittering rewards. Many men would enter the church if they could combine it with other occupations, or if they might quit it at pleasure, who refuse to enter into a path in which it is not permitted to turn back or to diverge. These are probably the principal causes which tend in this Country to keep down the number of clergymen. The revenue of the existing members is kept up by means of the fund set apart by law for their use, and somewhat equalized by the repeated intervention of the Legislature to raise the remuneration of curates by prohibiting the incumbent from offering, and the curate from accepting, a stipend as low as would have been fixed on mere principles of competition. The expense of entering the army is probably about equal to that of the church; for though about £600 is to be added for the price of the first commission and for outfit, the difference is about made up by the early age at which the profession can be begun. The expense of the navy is much less, and either profession may be entered upon without further preparatory study. The Legislature has fixed the pay and other advantages of the army and navy (moderate as they appear to be) much higher than would have been necessary to keep up the supply of qualified candidates. The difficulty of obtaining permission to enter either of them is so notorious, that few persons without considerable interest ever think of them. Yet, notwithstanding the influence of this feeling in diminishing the number of competitors, the Admiralty and the Horse Guards are besieged by candidates for first commissions ten times more numerous than the vacancies.

Political Economy.

Distribution. Inequalities of wages and profit in different employments.

The same may be said of what are the subjects of almost a distinct profession, public offices. Small as the emoluments are, if they are to be considered as repaying the expenses of education, they are objects of eager competition.

If further proof were wanted that the number of the candidates for the liberal professions is principally kept up by the feeling which forces every parent to endeavour to give to his children at least the education of his own rank rather than by calculation, it may be found in the abundance of governesses. The expense of giving to a girl the education which will fit her to be a governess, though not quite equal to that of educating a boy as a gentleman, is yet very considerable: no part of it is ever supplied by the public; and yet that profession is so overstocked with candidates that the pay scarcely equals that of a servant.

An expense of nearly £1000 beyond the common expense of a regular education may be necessary to start a young man as a physician, and perhaps nearly £1500 as a barrister. The lower branches of the legal and medical professions are about as expensive as the church or the army. But no branch of either law or physic admits of practice till after an apprenticeship of from three to five years, or of success, without three or four years of diligent study. The effect of all these causes has been so much to diminish the number of competitors in the medical and legal professions, that we much doubt whether they are now, as Adam Smith states them to have been in his time, under-recompensed in point of pecuniary gain. We speak more doubtfully as to medicine; but we can say, from the observation of many years, that his statement that, "if you send your son to study the law, it is at least twenty to one if he ever makes such proficiency as will enable him to live by the business," has no resemblance to the existing state of things. We have watched the progress of perhaps a hundred legal students, and, where fair diligence has been employed, success has been the rule, and failure the exception. Many, indeed, have not applied fair diligence: but we have seen much more success among the idle than failure among the laborious. So far from the chances being twenty to one *against* a young lawyer, we should be inclined to rate them at two to one in his favour.

3. Constancy of employment.

A third cause of variableness both in wages and in profits is constancy or inconstancy of employment. The variations which it occasions are, however, rather apparent than real. A London porter, employed for an hour, would think himself ill paid by less than a shilling. A pavior or a hodman, whose labour is much more severe, seldom receives more than 3*d*. an hour. But the pavior can always find a market for his services. At 3*d.* an hour, he can at an average earn three shillings a day, or about £46 a year. The porter may be sometimes a day without a job. If his employment be less regular by three-fourths than that of the pavior, to make his annual wages equal, his hourly wages must of course be three times as high. Adam Smith, indeed, thinks that his annual wages ought to be higher than the average, to make him some compensation for those anxious and desponding moments which the thought of so precarious a situation must sometimes occasion. But this evil is compensated, and, in most dispositions, more than compensated, by the diminution of his toil. We believe, after all, that nothing is so much disliked as steady, regular labour; and that the opportunities of idleness afforded by an occupation of irregular employment are so much more than an equivalent for its anxiety as to reduce the annual wages of such occupations to below the common average.

In the employment of capital, however, this compensation does not often exist. The occasional unproductiveness of his capital, generally speaking, affords no relief to the capitalist. It must, therefore, be compensated by a surplus profit, when productive, at least enough to balance its periods of unproductiveness. A house-builder's capital often lies unproductive; there are some places in which the majority of the houses are unoccupied for nine months in the year. The builder's profit during their occupation must be at least four times as great as if they were regularly inhabited. One of the consequences of the effect of irregularity of employment on wages and profits is to occasion many services and commodities to cheapen as the demand for them increases A man who can count on employment for four hours a day would be forced by competition to sell his services for nearly half of what he might have asked if he could have reckoned on only two hours. Prices in a watering-place always fall as the season becomes longer.

4. Trust. The fourth cause assigned by Adam Smith for the variation in wages, the small or great trust which must be reposed in the workman, appears to be in a great measure included in the second of his causes, the expense of education. Occasionally, indeed, we see persons receiving and deserving confidence though brought up under disadvantageous circumstances. The integrity of such persons must arise from a peculiarly happy natural disposition, and its reward may then be considered a species of rent; but, as a general rule, trustworthiness is the result of early moral cultivation, and in that case is as much to be considered a part of a man's immaterial capital as his prudence or his knowledge.

5. Probability of success. The last of the causes mentioned by Adam Smith, as affecting the remuneration of different employments, is the probability or improbability of success.

Uncertainty of success, in some respects, resembles inconstancy of employment. A few examples will show them to be different. The legal and medical professions are generally thought to be remarkably uncertain, but the employment of a successful physician or barrister is painfully incessant. On the other hand, a man may be morally sure that in a given occupation he will have a day's work forty or fifty times during a year, and that his earnings on those occasions will supply well his annual subsistence. Such an occupation would be certain, notwithstanding its inconstancy.

Uncertainty of success cannot well affect the wages of common labour, since no man, unless he be to a certain extent a capitalist, unless he have a fund for his intermediate support, can devote himself to an employment in which the success is uncertain. But its apparent, and indeed its real effect on *profits*, is very considerable.

Perfect knowledge, of course, excludes the idea of chance; but if all men had sufficient information to enable them to calculate fairly the chances of success, and were subject neither to rashness nor to timidity, it appears clear that even then the average profits of any employment would be raised by uncertainty of success.

When the sums are equal, to lose is obviously a greater evil than to gain is a good. If two men, with each a capital of £2000, toss up for £1000, the gainer augments his fortune by only one-third, and the loser sacrifices one-half. Laplace calculates the disadvantage at twenty-six per cent. At an equal game, he observes, the loss is relatively greater than the gain. Suppose a player with a fortune of 100 francs to risk 50 of them at heads and tails, his fortune, after he has deposited his stake, will be reduced to 87 francs; that is to say, 87 francs unhazarded would procure him as much happiness as 50 unhazarded, with 50 more subjected to the chance of being doubled or lost. Admitting this calculation to be correct, and admitting the existence of the degree of information and prudence which we have supposed, no one possessed of £10,000 would venture £5000 with an even chance of losing it, unless he had an even chance of gaining not merely £10,000, and an adequate profit on his capital of £5000, but could reckon on a further profit of £1300, as the price for undergoing the risk.

It is needless to say that men are far from possessing this degree either of information or of prudence. It is to be observed, however, that there are two sorts of uncertainty. In some cases the hazard is essentially connected with the employment itself, and recurs, in about an equal degree, at every operation. Smuggling, and the manufacture of gunpowder, are instances. Experience and skill may somewhat diminish the risk; but the best smuggler, and the best maker of gunpowder, probably each, suffers an average amount of loss. But there are employments in which success, if once obtained, is permanent. Such is often the case in mining. That mining is generally the road to ruin is notorious in all mining countries; but there are miners who have never suffered a loss. The same may be said of the liberal professions. Granting them to be as uncertain as Adam Smith believed them to be, the evil to which that uncertainty refers is experienced only by those who fail. To those who succeed they afford a revenue eminently safe and regular. Their uncertainty is personal. It arises from the error to which every man is subject when he compares his own qualifications with those of his rivals. If he be found on the actual trial inferior, his failure is irretrievable. In the other alternative his success is as permanent. Where any business is necessarily and permanently hazardous, the fortunes of any one individual engaged in it afford a sample from which we may estimate the fortunes of all. If only one old farmer could give to us all his personal experience, we should probably have a tolerably correct conception of the hazards to which farming is exposed. But, if we were to estimate the chances of legal or medical success from the average of ten or twenty selected instances, we should be likely to be grossly misled. The first sort of uncertainty, therefore, is likely to be estimated with a much greater approach to correctness than the second.

Adam Smith believed both to be under-estimated, and, consequently, that the average profits of all hazardous employments are below the average profits of safe ones. His views are stated with so much force and ingenuity, that we will extract them at considerable length.

"The overweening conceit which the greater part of men have of their own abilities is an ancient evil remarked by the philosophers and moralists of all ages. Their absurd presumption in their own good fortune has been less taken notice of. It is, however, if possible, still more universal. There is no man living who, when in tolerable health and spirits, has not some share of it. The chance of gain is by every man, more or less, overvalued; and the chance of loss is by most men undervalued; and by scarce any man, who is in tolerable health and spirits, valued at more than it is worth.

"That the chance of gain is naturally overvalued we may learn from the universal success of lotteries. The world neither ever saw, nor ever will see, a perfectly fair lottery, or one in which the whole gain compensated the whole loss, because the undertaker could make nothing by it. In the state lotteries the tickets are really not worth the price which is paid by the original subscribers, and yet commonly sell in the market for twenty, thirty, and sometimes forty per cent. advance. The vain hope of gaining some of the great prizes is the sole cause of this demand. The soberest people scarce look upon it as a folly to pay a small sum for the chance of gaining £10,000 or £20,000, though they know that even that small sum is perhaps twenty or thirty per cent. more than the chance is worth. In a lottery in which no prize exceeded £20, though, in other respects, it approached much nearer to a perfectly fair one than the common state lotteries, there would not be the same demand for tickets. In order to have a better chance for some of the great prizes, some people purchase several tickets, and others small shares in a still greater number. There is not, however, a more certain proposition in Mathematics, than that the more tickets you adventure upon, the more likely you are to be a loser. Adventure upon all the tickets in the lottery, and you lose for certain; and the greater the number of your tickets, the nearer you approach to this certainty.

"That the chance of loss is frequently undervalued, and scarce ever valued more than it is worth, we may learn from the very moderate profit of insurers. In order to make insurance either from fire or sea risk a trade at all, the common premium must be sufficient to compensate the common losses, to pay the expenses of management, and to afford such a profit as might have been drawn from an equal capital employed in any common trade. The person who pays no more than this evidently pays no more than the real value of the risk, or the lowest price at which he can reasonably expect to insure it. But, though many people have made a little money by insurance, very few have made a great fortune: and from this consideration alone it seems evident enough that the ordinary balance of profit and loss is not more advantageous in this than in other common trades, by which so many people make fortunes. Moderate, however, as the premium of insurance commonly is, many people despise the risk too much to care to pay it. Taking the whole kingdom at an average, nineteen houses in twenty, or rather perhaps ninety-nine in a hundred, are not insured from fire. Sea risk is more alarming to the greater part of people, and the proportion of ships insured to those not insured is much greater. Many sail, however, at all seasons, and even in time of war, without any insurance. This may sometimes, perhaps, be done without any imprudence. When a great company, or even a great merchant, has twenty or thirty ships at sea, they may, as it were, insure one another. The premium saved upon them all may more than compensate such losses as they are likely to meet with in the common course of chances. The neglect of insurance upon shipping, however, in the same manner as upon houses, is, in most cases, the effect of no such nice calculation, but of mere thoughtless rashness and presumptuous contempt of the risk. The ordinary rate of profit always rises, more or less, with the risk. It does not, however, seem to rise in proportion to it, or so as to compensate it completely. Bankruptcies are most frequent in the most hazardous trades. The most hazardous of all trades, that of a smuggler, though, when the adventure succeeds, it is likewise the most profitable, is the infallible road to bankruptcy. The presumptuous hope of success seems to act here as upon all other occasions, and to entice so many adventurers into those hazardous trades, that their competition reduces their profit below what is sufficient to compensate the risk. To compensate it completely, the common returns ought, over and above the ordinary profits of stock, not only to make up for all occasional losses, but to afford a surplus profit to the adventurers of the same nature with the profits of insurers. But if the common returns were sufficient for all this, bankruptcies would not be more frequent in these than in other trades." Book i. ch. x.

Whether Adam Smith's conclusions be true or false, they certainly do not follow from his premises. Bankruptcies might be frequent in a trade of extraordinary profit. We will suppose ten merchants each to employ for a year a capital of £10,000 in a remarkably safe trade, and ten others to employ equal capitals for the same period in a hazardous trade; and ten per cent. per annum to be the average rate of profit in undertakings involving similar trouble. The capital of £100,000 engaged in the safe trade would, at the end of the year, be raised to £110,000, but be distributed in the same proportions as before. If the capital engaged in the hazardous trade were also, at the end of the year, to amount to £110,000, it is clear that each trade would have been equally profitable, although a different distribution of the capital might have ruined some, and made the fortunes of others, among the merchants engaged in it. Two might have lost, and two others might have doubled, their whole property. If the capital in the hazardous trade were found, at the end of the year, to have been raised from £100,000 to £120,000, it is clear that the hazardous trade must have been twice as profitable as the safe one, though the whole of the advantage might have fallen to two or three or even to one of the supposed ten merchants, leaving all the others to bankruptcy.

Insurance was a still more unfortunate source of argument; for all the premises that it affords lead to a conclusion directly opposed to Adam Smith's. Insurance is one of the safest of employments. If its profits be remarkably moderate, their moderation can be accounted for only by the extra competition which its safety invites.

It affords, therefore, at least one example in favour of the superior profits of hazardous employments. Nor can it be said that the majority of persons despise the risk too much to secure themselves against it by paying a moderate premium. So much do they fear the risk that they are willing to guard against it by paying a most immoderate premium. The sum received by the insurance office must, as Adam Smith has remarked, exceed the value of the risk by an amount sufficient to pay the expenses of management, and afford ordinary profit. The sum received by the office on common insurances against fire is 1*s.* 6*d.* per £100; of which at least 6*d.* must go to pay expenses and profit, leaving 1*s.* as the value of the risk. But a duty is also paid to Government by the insured of 3*s.* per £100; so that the whole expense of insurance is 4*s.* 6*d.* per £100, or nearly five times the value of the risk. And, even at this extravagant rate, we believe that of good houses not one in a hundred is uninsured. So little do people despise the risk that, with their eyes open, they purchase a security against it at nearly five times its real value.

We suspect the fact to be that the imagination is unduly affected by the prospect either of enormous gain or of enormous loss; and, consequently, that men are ready to purchase the chance of obtaining a very great advantage, or the certainty of not suffering a very great disadvantage, at a price far beyond the value of either contingency. And this appears to be sufficiently proved by the facts which have been stated respecting insurance and lotteries. The English state lotteries of late times, indeed, afforded much more striking proofs of men's tendency to over-estimate the chances of extravagant gain than those which Adam Smith had seen. The tickets were always worth exactly £10 apiece—£10 for each ticket forming always a sum equal to the aggregate amount of all the prizes; the average price of a ticket was from £21 to £24 apiece. Instead of twenty or thirty per cent. the purchasers paid more than one hundred per cent. more than the value of their hope, just as, in the case of insurance, they pay nearly five hundred per cent. more than the value of their fear. The purchasers of tickets seem to have considered the relation between £24 and £20,000, not that between £24 and the one two-thousandth chance of getting £20,000. Just as those who insure their houses compare £2. 5s. with £1000 instead of comparing it with the one two-thousandth chance of losing £1000. Adam Smith has well remarked, that if the disproportion between the sum paid and the sum attainable were altered, even though the bargain were rendered more favourable, the competition for it would diminish. No one would buy half the tickets in a lottery, even at £12 a ticket; he would at once see the absurdity of paying £120,000 for an even chance of getting £200,000, though, if a state lottery were now opened, a folly just twice as great in kind would be committed by thousands. So if, instead of one in two thousand, which we believe to be about the present average, one house in ten were annually burned down, and the annual expense of insurance were £22 10*s.* per cent., insurance would diminish, though the terms would be twice as favourable as they now are.

Those employments which offer the possibility of a great return for a small outlay are of the nature of lotteries; and it may be supposed that they attract competition in proportion not so much to the real value of the contingency as to the excess of the possible return over the certain outlay. If that excess be very great, it may be supposed that the number of competitors in proportion to that of prizes will reduce so low the value of each man's contingency as to render such employments on the whole unprofitable. In this Country the church, the army, and the bar, are such employments. They offer prizes that may satisfy to its utmost almost every human desire; and they require, as we have seen, from those who have already received a gentleman's education, a very moderate further outlay: the church and the army scarcely any; the bar perhaps £1500. Under these circumstances, if the number of barristers were not kept down by the necessity of years of irksome study, and the emoluments of the church and of the army and navy kept up by the funds appropriated to their respective use, we have no doubt that the competition in these professions would reduce their average profit far below even its present moderate amount. We often hear proposals for equalizing, or rather for diminishing, the inequality in ecclesiastical preferments. At first sight it appears a waste to pay £20,000 a year to an Archbishop for doing less than is required from the curate of a populous parish with only £100 a year. But if our object were to obtain an expensively educated clergy on the cheapest terms, that object would probably be best effected, not by diminishing, but by increasing, the value of the highest prizes. The revenues of all the English Bishoprics put together fall short of £150,000 a year. This sum, divided among the ten thousand livings, would raise the value of each by £15. Can any one believe that such a change would not diminish the worldly attractions of the church? Nothing sells so dearly as what is disposed of by a well-constructed lottery, and if we wish to sell salaries dearly, that is, to obtain as much work and knowledge as possible for as little pay as possible, the best means is to dazzle the imagination with a few splendid prizes, and, by magnificently overpaying one or two, to induce thousands to sell their services at half price.

We have been told that it was once proposed at Rome, as the easiest mode of constructing a vast dome, to raise a mound of earth of the required shape, and build over it. But the expense of then removing the earth appeared enormous. On the principle which we have endeavoured to illustrate it was proposed that in raising the mound the earth should be irregularly mixed with coins of gold, silver, and copper, amounting in the aggregate to a sum equal to about half the aggregate amount of the wages which it would have cost to remove it by paid labourers, and then to allow the populace to remove it in barrows, without payment. It was supposed that a sufficient number of persons would offer their services, though, in fact, working, in the aggregate, at half price.

We have already expressed an opinion that the bar is better paid than the church, and we attribute this to its being less of a lottery. The expenditure, as we have seen, is far greater, and the prizes, on the whole, are smaller. The learned profession which offers the fewest prizes and requires the largest outlay, that of a schoolmaster, as it ceases to be a lottery, is by far the best paid. There are probably few capitals which in the aggregate yield so certain and at the same time so large a profit.

In some few cases commercial adventures are of the nature of a lottery. Such were the shares which excited the strange fevers of cupidity and speculation which marked the years of 1720 and 1825. Of the thousands who crowded to buy Chili and Peruvian, and Rio la Plata, and Columbian, and Mexican shares, how many can be supposed not to have ascertained, but to have endeavoured to ascertain, or even to have thought of ascertaining, the probability of their Company's success? All they knew was that Real del Monte shares, for which £70 had been given, were selling for £1200: and they bought a few shares in other Companies, because, if the speculation succeeded, they might get one thousand per cent., and if it failed they had only lost one or two hundred pounds.

Generally speaking, however, those commercial adventures which offer a large immediate advantage are more in the nature of ordinary gambling than of a lottery. The possible loss often equals or exceeds, and generally bears a large proportion to, the possible gain. The undue hopes and the undue fears, which we have described as excited by the prospect of enormous gain and enormous loss, may now be supposed to balance one another, and to leave room for the action of Adam Smith's principle, an absurd presumption in our own good fortune. If his theory be correct, if every man in tolerable health and spirits have a tendency to miscalculate the chances in his own favour, it must follow that those speculations, which offer a great gain at the hazard of a great loss, invite so much competition as to be, if not positively unprofitable, at least less advantageous than ordinary employments. And we believe such to be the case. Mining and stock-jobbing are employments of capital which offer splendid success at the hazard of ruinous failure. The former employment is notorious not merely as affording less than average profits, but as affording no aggregate balance of profit at all as productive in the aggregate of loss. Knowledge, diligence, capital, all the materials of success, are applied in Cornwall to one of the richest mineral districts in the world, and yet it is supposed that the aggregate price of the whole of the copper and tin annually raised in Cornwall is not equal to the whole of the expense of raising it. A few capitalists, however, make large fortunes, and their success draws on the rest, generally to loss, often to ruin.

Even if speculation in the funds were attended by no expense, it is mathematically certain that it could in the aggregate afford no profit, as what is gained by one must be lost by another. But it is carried on at a very great expense. Every transfer costs a commission of 2*s.* 6*d.* for every £100 stock. A man who annually buys and sells stock to the amount of £800,000, and that is far from a large amount for an habitual speculator, must at an average pay for commission £1000 a year; and that £1000 exactly represents the amount of his annual loss, supposing him to speculate with average success.

On the whole, however, though we attribute something to men's confidence in their superior good fortune, we attribute much more to their confidence in their superior ability. A confidence which, if universal, would, *on the whole*, produce as much miscalculation as the former, but which is not obviously irrational in *each particular instance*, and on that very account is stronger and more general.

The third and last class of the employments of capital which are subject to uncertainty comprises those which are just the reverse of a lottery: those in which the gain is in each instance small, but nearly certain; and the loss great, but highly improbable.

If our theory be correct, this remote contingency of great loss must in general be overvalued, and the capitalist who submits to it must, in addition to the profit which would content him if his business were perfectly safe, receive at an average in the first place an extra profit equal to the risk, and in the second place, a further profit to compensate his anxiety, to compensate the excess of evil occasioned by loss over the benefit that attends on gain, and a still further profit to compensate the undue importance which he is likely to attribute to the chances against him.

Now this class comprises almost all those employments of capital which, to distinguish them from those attended by extraordinary risk, are generally termed safe. A merchant or a manufacturer who wishes to be safe must in general give up the hope of obtaining great profit by any single transaction. But no productive employment of capital can be *perfectly* safe. A capitalist may, indeed, *lend* his capital to one who wishes to employ it, on receiving a pledge, and the pledge may so much exceed in value the sum lent as to make the loan secure; but the capital itself, if employed, must be risked. Credit must be given, confidence must be reposed in agents, and when every precaution has been taken, an extraordinary season, an unexpected source of supply, a sudden change in foreign or domestic politics, or a commercial panic, may produce ruin out of the best-arranged operations. No man in business can be perfectly sure that in ten years' time he shall not be a bankrupt. If we are right, this risk of enormous loss, when unbalanced by the hope of enormous gain, must be compensated by an extra profit of something more than its value, just as the chance of enormous gain, when not balanced by the fear of enormous loss, is purchased at more than its value; and as the latter class of employments gives a smaller, so the former must give a greater average return than would be afforded by an employment perfectly safe, if any such there be.

Inequalities in wages and profits occasioned by the difficulty of transferring capital and labour from one employment to another.

The inequalities in wages and profits which we have as yet considered arise from causes inherent in the employments themselves which have been the subjects of discussion, and would, generally speaking, exist even if one occupation could at will be exchanged for another. But great inequalities are found which cannot be accounted for by any circumstances leading men to prefer one employment to another, and which therefore continue only in consequence of the difficulties experienced by the labourers and the capitalists in changing their employments.

The difficulty with which labour is transferred from one occupation to another is the principal evil of a high state of civilization. It exists in proportion to the division of labour. In a savage state almost every man is equally fit to exercise, and in fact does exercise, almost every employment. But in the progress of improvement two circumstances combine to render narrower and narrower the field within which a given individual can be profitably employed. In the first place the operations in which he is engaged become fewer and fewer. "In a pin-manufactory," says Adam Smith, "one man draws out the wire, another straightens it, a third cuts it, a fourth points it, a fifth grinds it at the top for receiving the head: to make the head requires two or three distinct operations; to put it on is a peculiar business; to whiten the pins is another; it is even a

Distribution. Inequalities of wages and profit in different Countries.

trade by itself to put them into the paper; and the important business of making a pin is in this manner divided into about eighteen distinct operations." In a large manufactory the man who is engaged in one of these operations has little experience in any of the others.

And, in the second place, the skill which the division of labour gives to each distinct class of artificers generally prevents whatever peculiar dexterity an individual may have from being of any value in a business to which he has not been brought up. A workman whose specific labour has ceased to be in demand finds every other long-established employment filled by persons whose time has been devoted to it from the age at which their organs were still pliable and their attention fresh.

Mr. Ewart, one of the many intelligent witnesses examined by the Committee on Artisans and Machinery, is asked:

"Can you state any facts to prove the inefficiency of even the best workmen when they are taken out of the immediate line of their daily business, though in the same trade?"

He replies, "Yes, I can: I should state particularly the case of the clock and watch tool and movement makers in Lancashire; they are considered the best workmen; they use the same sort of tools that the cotton-machine makers use; but they are brought up to no employment but making those clock and watch tools and movements. When those men come to be employed in making cotton machines we find that they have almost as much to learn as if they had never learnt any working in metal at all. We have found them quite insufficient to do any ordinary filing and turning."*

Garnier, in the amusing notes to his translation of Adam Smith, contrasts the comfort of the lower orders in France with the pauperism of England, and ascribes the difference which he discovers to artificial restraints on the circulation of labour in England, and the absence of such restraints in France. "Under a government," he observes, "which does not interfere with the direction of industry, it is impossible that a man in health and strength can be without employment, unless his vices make employment intolerable to him. Let the workman be allowed to choose the market for his labour, and you may be sure that he will find one, and more and more certainly in proportion to the wealth of the Country. The complaint of want of work is the threadbare excuse of the idler who prefers relief to wages. If he were to search for it, he would find it as well as his companions. In France, though our population is one-third more numerous than that of England, and the fund for the support of labour much smaller, the labouring classes are free from want, or even discomfort."†

There can be no doubt that we have among our institutions and our habits much that fetters and misdirects the industry of our labourers; and that these causes frequently occasion, and always prolong, the want of employment to which large portions of our labourers are frequently exposed. We believe, too, that from many of these causes France is comparatively free. The monopolies possessed by towns and by incorporated bodies of artificers, with their oppressive bye-laws and duties, were swept away by the Revolution. Much, however, that is productive of evils similar in kind, still remains. Not long ago the number of butchers in Paris was, by an ordonnance of police, restricted to four hundred. The most important of all employments, that of affording education, is a government monopoly; and the commercial code of France is even worse than our own. If, therefore, the labouring classes of France never suffer from want of employment, they do not owe their immunity to a complete, or even a very considerable, freedom from interference. If their employment be actually more constant than that of our labouring classes, we believe that they owe that constancy principally to the inferior extent of their manufactures, and, what is both the cause and the effect of that inferiority, to a much less subdivision of labour. Less than one-third of the population of England, and more than two-thirds of the population of France, are employed in the cultivation of the soil. We are inclined to think that, notwithstanding this disproportion, the English labouring classes are better fed than the French. But there is no comparison between their respective enjoyment of clothing and other manufactures. The greater part of the coarser manufactures are both cheaper and better in England; while the wages in France, both of manufacturing and agricultural labourers, are about half what they are with us. "A peasant suffering severely from rheumatism," says M. Say, (*Cours Complet*, tome i. p. 46,) "asked my advice. I recommended to him a flannel waistcoat next the skin. He did not know that there was such a thing as flannel. I told him then to wear under his shirt a cloth waistcoat turned inside-out. How, he asked, am I to get cloth to wear under my shirt, when I have never been able to afford to wear it above? And yet he was no worse off than his neighbours."

The French labourer, being employed in more capacities than the Englishman, has more trades to turn to, and for that very reason is less efficient at any one. The Russian is probably more seldom out of employ than the Frenchman, and the Tartar less frequently than either. But few principles are more clearly established than that, *cæteris paribus*, the productiveness of labour is in proportion to its subdivision, and that, *cæteris paribus*, in proportion to that subdivision must be the occasional suffering from want of employment. A savage may be compared to one of his own instruments, to his club, or his adze, clumsy and inefficient, but yet complete in itself. A civilized artificer is like a single wheel or roller, which, when combined with many thousand others in an elaborate piece of machinery, contributes to effects which seem beyond human force and ingenuity, but, alone, is almost utterly useless.

The difficulty in transferring *material* capital from one employment to another depends principally on the degree in which it has been manufactured, and on the change to be made in the disposition of its parts. The destination of raw material can, in general, be changed with little inconvenience. The stones that have been collected for a bridge may easily be employed for a house. But if they have been formed into a house, or a bridge, the value of the materials would scarcely pay the expense of removing them. Those costly instruments which form the principal part of fixed capital can scarcely ever be applied in their original state to any but their original purposes. They are employed, therefore, in the same way, long after they have ceased to afford average profit on the expense of their construction, because a still greater loss would be incurred by attempting to use them in a different manner. It would be a bad speculation to erect a steam-engine at the cost of £20,000 which should return an annual profit of only £100, but it would be a still worse one to sell it as old iron for £500.

---

* *Report on Artisans and Machinery*, 1824, p. 251.

† Note 25.

There is a considerable resemblance in this respect between mental and inanimate capital. Probity, industry, judgment, elementary knowledge, and the other moral and intellectual habits and acquirements to which we give the general name of a "good education," are a kind of mental raw material, of which the destination can be altered at pleasure. The peculiar knowledge and habits of a given profession are like a steam-engine or a water-mill, of comparatively small value for any but their appropriate purposes. In general, however, mental capital is the more transferable of the two, and becomes more and more so the more exclusively it *is* exclusively mental. The professional knowledge and dexterity of a weaver would be of little use to him in any other employment. A lawyer or a physician, prevented by circumstances from continuing to practise, would find the information and the intellectual habits which he had acquired in his former profession of considerable advantage in any new one. Bodily labour, especially when the labourer is confined to a very few operations, so that a few muscles have too much and the rest too little to do, often weakens, and almost always distorts, the frame. Mr. Shaw, a surgeon of great eminence in the treatment of distortion, told us that, as he walked along the streets, he could in general tell each man's trade by his characteristic deformity. But mental exertion, unless in those rare cases in which it is carried to such an excess as to produce cerebral derangement, never seems to weaken the mind. It may sometimes, perhaps, a little distort it, may sometimes give to one or two faculties an undue preponderance; but even this, to such an extent as to diminish the productiveness of the individual's subsequent exertions, is comparatively rare. And, in general, it will be found, that the more work a man's mind has done, the more he is able to do, and the better he will do it.

The obstacles which exist, even within the same neighbourhood and the same Country, to the transfer of labour and capital from one employment to another, are of course aggravated, when not only the occupation but the neighbourhood or the Country is to be changed. Adam Smith states the common price of labour in London and its neighbourhood to have been, when he wrote, 1*s.* 6*d.* a day, and the usual price in the Lowlands of Scotland to have been 8*d.* "Such a difference of prices," he adds, "which it seems is not always sufficient to transport a man from one parish to another, would necessarily occasion so great a transportation of the most bulky commodities, not only from one parish to another but from one end of the kingdom, almost from one end of the world, to another, as would soon reduce them more nearly to a level. After all that has been said of the levity and inconstancy of human nature, it appears evidently from experience, that a man is, of all sorts of luggage, the most difficult to be transported." Book i. ch. vi.

When we compare the wages of labour in different Countries, we usually estimate them in money. And we are forced to do this for two reasons: first, because the precious metals are the only important commodities universally distributed throughout the world; and, secondly, because they are the only commodities of which the value is every where the same, or very nearly the same. We should gain little information by comparing the number of pine-apples that can be earned in Java and in England by a week's ordinary labour. And still less by comparing the quantity of pulque earned by a Mexican with the quantity of whisky earned by an Irishman. But money wages, though they measure accurately the value of national labour in the general market of the world, afford a very imperfect test of the degree of comfort and convenience obtained by the labourer in different Countries. Now it is this difference, not the difference in money wages, that leads him to change his residence; and we can ascertain, or rather approximate to ascertaining, these differences only by translating the money wages in different Countries into the commodities used by the labourer. The money wages of labour in North America are about one-third higher than in England; this is in some measure compensated by the higher price of manufactures. But as food, which every where forms the largest portion of the labourer's expenses, is considerably cheaper than with us, the real superiority of the American over the English labourer is greater than is indicated by the difference in their wages. We are told (Crawford's *Embassy*, p. 468) that a day labourer in Bengal can hardly earn £3 a year. Notwithstanding this low rate of wages, most manufactures are dearer there than in England. Food, of course, is cheaper; for were it at the same price as the cheapest food in England, a family could not exist at about 1*s.* a week. And it is obvious that in every Country the average wages of labour must be sufficient to support an average family. In proportion to the quantity of land and labour required, rice is, perhaps, the most abundant food that the earth affords. Rice, therefore, is the food of the Bengallee, and his wages, supposing them to be all laid out in food, would produce him about eight hundred pounds; the same quantity of rice might be purchased *here* for about £10 sterling. Estimated in money, therefore, wages in England, at £30 a year, are ten times as high as in Bengal; estimated in manufactures, they are more than ten times; estimated in rice, they are about three times as high.

In comparing the rate of profits in two Countries, this difficulty does not exist; both the advances and the returns being always estimated in money, the apparent must be the real difference between the rate of profits in any two Countries.

The great obstacles to the circulation of labour are difference of climate, distance of place, and difference of language. The first is by far the most powerful, and is so great that there is little voluntary emigration of labourers to a very dissimilar climate. Difference of language seems often a greater obstacle than very considerable distance of place. The advance of wages obtained by an English mechanic in France is greater than he can get by going to America; but ten go to America for one who will venture to France. Differences in habits, government, and religion are comparatively weak obstacles, except in those cases where the differences have caused an antipathy, making immigration dangerous. Few Countries differ more in habits and religion than England and Ireland, or in government than Ireland and the United States. Yet we know how great is the emigration from Ireland to both those Countries. In general, however, the physical and moral obstacles to the emigration of single labourers, or even of bodies of labourers, unless supported and directed by a very considerable capital, are such that it seldom takes place unless under peculiar circumstances; such as those of Ireland and England, or Ireland and America, where the temptation is very great, the physical obstacle only a passage of a few weeks in the one case, and a few hours in the other, and the language the same.

Political Economy.

Distribution. Inequalities of wages and profit in different Countries.

But the voluntary migrations of capitalists and labourers united, and the attempts by capitalists to force the involuntary migration of labourers, have been among the principal causes that have advanced and retarded the improvement of mankind. To the first class belong those hostile migrations in which a whole nation, in the hope of obtaining a climate or a soil more favourable to production, has moved in a body to seize the territory of a neighbour. From the invasion of Egypt by the Shepherd Kings to that of Greece by the Turks these movements have kept the inhabitants of the whole of our hemisphere in a constant fluctuation. Many Countries, and among them our own, have been so covered by successive strata of occupants, that no trace of the first settlers can be discovered; in others, the poor remains of the aborigines are discovered, like the Helots of Laconia, the Fellahs of Egypt, or the Bheels of Hindostan, by their misery and degradation. Europe, in its present state, does not fear these invasions. They could not be attempted by a civilized nation, nor, in the present state of the art of war, could they be successful *against* one. But, until the improvement of military science and the extensive use of machinery in war, gave to wealth and knowledge their present superiority, these attributes seem to have been sources rather of weakness than of strength. The least polished people seem, on the whole, to have had the advantage. Cicero confesses the warlike superiority of the Gauls over the Romans. It was not till after Gaul had become comparatively civilized that her military fame was recalled as a tradition.* A few centuries of peace made the Britons an easy prey to the Saxons, and the Saxons to the Danes. Under such circumstances the permanent improvement of the human race seemed almost hopeless. And if gunpowder had not been brought into use just at the time when those military virtues which belong to semi-barbarism were decaying, it appears probable that another irruption of barbarians might have brought back another middle age, in which Europe might have lost all that she gained between the XIIth and the XVth Centuries.

Resembling in kind these migratory invasions, but very different from them in effect, have been those emigrations on a smaller scale, to which we give the name of colonization; in which a portion of a comparatively civilized nation have gone out, with their knowledge and wealth, their material, and moral, and intellectual capital, and settled in an unoccupied or thinly peopled district. It is a remarkable and a most unhappy circumstance that, notwithstanding the progress of political knowledge, the true principles of colonization have been less and less understood, or, if understood, less and less acted on, as civilization has advanced. The earliest colonies with which we are acquainted, those founded by the Phœnicians and the Greeks, seem to have been founded for the benefit of the colonists. They were allowed to appoint their own governors, to direct their own industry, and to manage their own concerns; and they relied on themselves for their defence. They were children, but emancipated children; and their progress was in proportion to their independence. The Phœnician colonies in Africa and Syria, and the Grecian colonies in Italy, Thrace, Sicily, and Asia, seem quickly to have risen to an equality with, or to have surpassed, their Mother Countries; to have obtained, in fact, all the wealth and power which their extent of territory, and the religion and knowledge of the times, made it possible to acquire. The Roman colonies scarcely deserve that name. They were generally formed by grants of the lands, the capital, and the persons of conquered Tribes, almost as civilized as their conquerors, to the armies or to the populace of Rome, as a reward for services in foreign or civil war, or for sedition and riot in the forum. It may be a question whether they accelerated or retarded the improvement of the world.

The colonies of modern Europe have been established partly for the benefit of the colonists, and partly, as it was supposed, for that of the parent state. The latter has, in general, contributed a part of the expense of outfit, and almost all the expense of protection against foreign aggression. She has also, in general, given to her colonies a monopoly, or something approaching to a monopoly, of her market. On the other hand, she has, in general, required her colonies to give to her own productions a much stricter monopoly. She has, in general, required her colonies to receive European productions solely from the Mother Country, and to export only to the Mother Country colonial productions. She has, in general, appointed the principal officers, and interfered in the internal management of her colonies. She has not only prohibited the colonists from purchasing in any other market what could be produced in the Mother Country, but has prohibited them from producing for themselves. She has peopled them with the refuse of her gaols, and governed them by the refuse of her aristocracy. The Court of Spain commanded the vineyards of Mexico to be rooted up; the English Parliament forbade Jamaica to discontinue the slave-trade, prohibited the establishment of iron, woollen, and hat manufactures in our North-American colonies, and even now forbids the West Indians to refine their own sugar. The Mother Country dragged the colonists into all her wars, and, from their comparatively defenceless situation, exposed their trade to more loss, and their persons and property to more danger, than she encountered herself. And when the rising strength of the colony rendered these oppressions intolerable, no Mother Country has yet had the good sense to submit quietly to a separation, which, even if it could have been avoided, might have been desirable; and which, whether expedient or not, was inevitable. England, France, Portugal, and Spain have all wasted, in the vain attempt to retain their colonies, ten times more wealth than was expended in founding them.

But, mismanaged as colonies have been, they have, without doubt, been one of the principal means by which civilization has been diffused.

The separate attempts by independent capitalists to procure the voluntary emigration of labourers have generally been made on a small scale, and have been unprofitable to the undertakers, in consequence of the difficulty of compelling or inducing the labourers to perform their engagements, and work diligently at a rate of wages sufficiently inferior to the current rate of the colony to repay the expense and risk of the capitalist. Sir R. Wilmot Horton's plans for effecting emigration on an extended scale, and as a national undertaking, have not received the attention which the magnitude of the probable advantage, and the unwearied diligence and public spirit of its proposer, deserved. And the scheme for founding in Australia a colony in which the first price of all the land shall be employed in

Political Economy.

Distribution. Inequalities of wages and profit in different Countries

---

* *Gallos in bello floruisse audivimus.*

Distribution. Inequalities of wages and profit in different Countries.

transporting labourers, has not yet been submitted to the test of experience.

The attempts by capitalists to force the involuntary migration of labourers have been productive of almost unmixed evil. They produced, and have continued, the abominable traffic in which *man* is the commodity;—a traffic which, partly by its direct effects, and partly by the wars and general insecurity which are its necessary accompaniments, retarded more than any other cause the early civilization of Europe; has kept, and continues to keep, the greater part of Asia, and the whole of Africa, in hopeless barbarism; and has divided the inhabitants of the most fertile portions of the Continent of America, and, until lately, those of almost all her islands, into two classes only, the oppressors and the oppressed.

The transfer of *capital* from one Country to another is subject to less difficulty. When the exchange is at par between any two Countries, capital can be transmitted in the shape of money without any expense. And as the occasional loss which occurs when the exchange is against the Country to which it is to be exported is compensated by the occasional gain when it is in favour of that Country, it may fairly be said that monied capital is transferred from Country to Country without expense. The chief obstacle is the unwillingness of capitalists either to trust their capital out of their own superintendence, or to encounter a change of government, habits, climate, and language, by accompanying it. Difference of language, however, is felt as a slight objection by educated men. Nor is difference of government of great importance to those who propose only a transitory residence. The difference indeed is often considered an advantage. During the late war, London was filled by foreign capitalists, whose principal motive was to escape the tyranny of Napoleon. Differences of habits and climate are more material, especially the latter; but even these do not seem to counterbalance a great increase of profit. There is scarcely a port in the civilized world in which a considerable part of the mercantile class does not consist of the natives of Great Britain. The inequality in the rate of profit throughout the civilized world is, therefore, much less than the inequality of wages. And as the general progress of improvement tends more and more to equalize the advantages possessed by different Countries in government and habits, and even in salubrity of climate, the existing inequalities of profits are likely to diminish.

Political Economy.

Distribution. Inequalities of wages and profit in different Countries.

CONTENTS.

POLITICAL ECONOMY defined as, The Science which treats of the NATURE, the PRODUCTION, and the distribution of WEALTH, 129.
WEALTH defined, as comprehending all those things, and those things only, which are *transferable, limited in supply*, and directly or indirectly *productive of pleasure or preventive of pain*, or, to use an equivalent expression, *which are susceptible of exchange*, or, to use a third equivalent expression, *which have value*, 131.
Constituents of WEALTH:—
  1. *Utility*, 131.
  2. *Limitation in supply*, 131.
  3. *Transferableness*, 132
  Limitation in supply the most important, 133.
VALUE defined as, *The quality in any thing which fits it to be given and received in exchange*, 134.
The *intrinsic* causes of the value of a commodity defined as, Those which give to it utility and limit it in supply.
The *extrinsic* as, Those which limit the supply and occasion the utility of the commodities for which it is to be exchanged, 134.
Steadiness in value depends on the permanence of the *intrinsic* causes of value, 137.
Objections to the definition of wealth considered, 137.
Statement of the *four elementary propositions of the Science*:—
  1. *That every man desires to obtain additional wealth with as little sacrifice as possible.*
  2. *That the population of the world, or, in other words, the number of persons inhabiting it, is limited only by moral or physical evil, or by fear of a deficiency of those articles of wealth which the habits of the individuals of each class of its inhabitants lead them to require.*
  3. *That the powers of labour, and of the other instruments which produce wealth, may be indefinitely increased by using their products as the means of further production.*
  4. *That, agricultural skill remaining the same, additional labour employed on the land within a given district produces in general a less proportionate return, or, in other words, that though, with every increase of the labour bestowed, the aggregate return is increased, the increase of the return is not in proportion to the increase of the labour*, 139.
Developement of the first elementary proposition, namely, *the general desire of wealth*, 139.
Developement of the second elementary proposition, namely, *the causes which limit population*, 140.
Production defined as *the occasioning an alteration in the condition of the existing particles of matter, for the occasioning of which alteration, or for the things thence resulting, something may be obtained in exchange. This alteration is a product*, 149.
Products divided into *services* and *commodities*. A *service* is the *act* of occasioning the above-mentioned alteration. A *commodity* is the *thing as altered*, 150.
Consumption defined as *the making use of a thing*, 151.
Productive consumption defined as *that use of a product which occasions an ulterior product*. Unproductive consumption as *that use which occasions no ulterior product*, 151.
Instruments of production:—
Primary, 1. labour; 2. natural agents, 152.
  1. *Labour* defined as *the voluntary exertion of bodily or mental faculties for the purpose of production*, 152.
  2. Natural agents defined as *those productive agents which do not derive their powers from man*, 152.
  3. Third and secondary instrument of production. *Abstinence.* Abstinence defined as *the conduct of a person who either abstains from the unproductive use of what he can command, or designedly prefers the production of remote, to that of immediate, results*, 153.
Abstinence, combined with one or both of the other two instruments of production, occasions the existence of *capital*. *Capital* defined as *an article of wealth, the result of human exertion, employed in the production or distribution of wealth*, 153.
Different modes in which *capital* may be employed, 153.
Statement of the advantages derived from the use of capital.
  1. The use of *implements*, 156.
  2. The *division of labour*, 159.
  Under these heads the third elementary proposition of the Science is developed.
Additional labour when employed in manufactures is *more*, when employed in agriculture is *less*, efficient in proportion, 162.
Developement of the fourth elementary proposition of the Science.
DISTRIBUTION.

Society divided into *three classes, labourers, capitalists, and proprietors of natural agents*, each class having a different *instrument*, a different *conduct*, and a different *remuneration*, 165.
Nomenclature applicable to the first class, the *labourers*, 165.
Nomenclature applicable to the second class, the *capitalists*, 165.
Nomenclature applicable to the third class, the *proprietors of natural agents*, 166.
EXCHANGE.
Cost of production defined as *the sum of the labour and abstinence necessary to production*, 170.
Divided into cost of production on the part of the *producer*, and cost of production on the part of the *consumer*, 170.
These are the same, unless the production be subject to a *monopoly*, 171.
Monopolies divided into four kinds:—
1. A monopoly under which the monopolist has not the exclusive power of producing, but exclusive facilities as a producer which may be employed indefinitely with equal or increasing advantage, 171.
2. A monopoly under which the monopolist is the only producer and cannot increase the amount of his produce, 172.
3. A monopoly under which the monopolist is the only producer and can increase indefinitely with equal or increasing advantage the amount of his produce, 172.
4. A monopoly under which the monopolist is not the only producer, but has peculiar facilities which diminish and ultimately disappear as he increases the amount of his produce, 172.
The last is the great monopoly of land, 172.
Effects of the cost of production on price, 175.
Effects of monopolies on price, 176.
Consequences of the proposition that additional labour when employed in manufactures is *more*, and when employed in agriculture is *less*, efficient in proportion.
I. Different effects of increased demand on the prices of manufactured, and of raw, produce, 178.
II. Different effects of taxation on the prices of manufactured, and of raw, produce, 179.
Discussion whether certain revenues ought to be called rent, profit, or wages, 182.
Causes on which the *proportionate amount of rent* depends, 185.
Discussion of the circumstances which decide what, at a given time and in a given place, shall be the average rate of wages and the average rate of profit.
Statement of the question, 188.
Meaning of the words *high* and *low* as applied to *wages*, 188.
Difference between the *amount of wages* and the *price of labour*, 191.
Proximate cause deciding the rate of wages stated to be *the extent of the fund for the maintenance of labourers compared with the number of labourers to be maintained*, 193.
Discussion of seven opinions inconsistent with this proposition:—
1. The doctrine that the rate of wages depends solely on the proportion which the number of labourers bears to the amount of *capital* in the Country, 193.
2. The doctrine that wages depend on the proportion borne by the number of labourers to the whole *revenue* of the society of which they are members, 193.
3. The doctrine that the non-residence of unproductive consumers can be detrimental to the labouring inhabitants of a Country which does *not* export raw produce, 193.
4. The doctrine that the general rate of wages can, except in two cases, be diminished by the introduction of machinery, 196.
5. The doctrine that the general rate of wages can be reduced by the importation of foreign commodities, 199.
6. The doctrine that the unproductive consumption of landlords and capitalists is beneficial to the labouring classes because it furnishes them with employment, 199.
7. The doctrine that it is more beneficial to the labouring classes to be employed in the production of services than in the production of commodities, 200.
Statement of the causes on which the extent of the fund for the maintenance of labourers really depends. 1. The productiveness of labour in the direct or indirect production of the commodities used by the labourers. 2. The number of persons directly or indirectly employed in the production of things for the use of labourers compared with the whole number of labouring families, 201.
I. Causes on which the productiveness of labour depends:—
1. The corporeal, intellectual, and moral qualities of the labourer, 202.
2. The assistance of natural agents, 202.
3. The assistance of capital, 202.
4. The existence or the absence of government interference, 202.
II. Causes which divert labour from the production of commodities for the use of labouring families:—
1. Rent, 204.
2. Taxation, 205.
3. Profit, 206.
Profit consists of the difference between the value of the advance made by the capitalist and the value of the return, 207.
How that value should be estimated, 206.
The facts which decide in what proportions the capitalists and labourers share the common fund after the deduction of rent and taxation stated to be two: first, *the general rate of profit in the Country on the advance of capital for a given period*: and, secondly, *the period which in each particular case has elapsed between the advance of the capital and the receipt of the profit*, 206.
Cause regulating the rate of profit ascertained to be *the proportion which the supply of capital employed in providing wages bears to the supply of labourers*, 209.
Causes regulating the period of advance incapable of a general statement, 210.
Capitalists and labourers interested in the period of advance only so far as they are consumers, 211.
Causes of variation in the amount of wages and the rate of profits in different employments of labour and capital assigned by Adam Smith:—
1. Agreeableness, 212.
2. Facility of learning the business, 214.
3. Constancy of employment, 215.
4. Trustworthiness, 216.
5. Probability of success, 216.
Variations occasioned by the difficulty of transferring labour and capital from one employment to another, 219.
From one country to another, 221.

CARPENTRY.

CARPENTRY is the Art of preparing timber principally for the construction of building.

In the following Essay we shall first treat on the nature and properties of timber; we shall then proceed to the practical application of timber to Carpentry, and to the principles and practice of geometrical operations required in working drawings, in order to effect the construction of buildings in the easiest and most substantial manner.

Various Kinds and Properties of Timber.

Timber is obtained either from the trunks or branches of trees. The trunks of trees approach to the figure of the frustum of a cone not differing materially from that of a cylinder, the difference of the diameters at the ends being generally very small. In order, therefore, to describe the properties of timber we shall suppose that, when it is cut into such trunks, the figure of each trunk is that of the frustum of a cone, of which the diameters of the circular ends even of very long pieces do not differ considerably.

When timber is split by any straight-edged instrument, the surfaces which are separated are very nearly in planes, and would pass through the vertex of the cone were the upper part restored; and as the splitting may be made both in parallel and in transverse planes so as to form bars which shall have the areas of their sections as small as we please, the bars may have their right sections as small as threads; such threads are called *fibres*, and timber which has the property of splitting into such small rectilinear parts is said to be straight grained.

If two square bars of equal lengths and breadths be cut from the same trunk or stem of a tree, the length of one of the bars being in the direction of the fibres, the length of the other perpendicular to the fibres, the transverse strength of the bar, of which the length is in the direction of the fibres, would exceed the transverse strength of the bar, of which the length is perpendicular to the fibres, several times; by some experiments the longitudinal bar is three times as strong as the transverse bar. Moreover, a timber bar, of which the length is in the direction of the fibres, will also resist the force of extension or that of compression with much greater effect than when the length is perpendicular or oblique to the fibres. Hence, since timber must always be employed either to resist transverse, extending, or compressing forces, it is always divided for use in the direction of the fibres into bars of various dimensions; and whenever the right section is spoken of, this section will always be supposed perpendicular to the longitudinal arrises, or because the longitudinal arrises are in the direction of the fibres, the right section will be perpendicular to the fibres; moreover, if a bar be rectangular, the dimensions of the right section will be equal to the lengths of two adjacent sides of the rectangle which is the right section of the bar.

Durability and use of oak.

Of timber materials none is more durable than oak; some others are, however, less expensive and easier to work, and are, therefore, preferred on that account. Oak, therefore, is used only occasionally in small quantities.

The general use of fir in building.

Among the timbers which are more easily wrought, fir is the most useful, on account of its durability and strength, the straightness of its fibres, as also the ease by which it may be formed into various figures or cut in every direction. We shall, therefore, direct our attention principally to this species of timber, but not to that of the growth of our own Country, which is not only weaker, but more subject to decay than foreign timber.

Timber is imported into Britain from the North of Europe and from North America. European fir is distinguished by the names of the places from which it is cut; *viz.* Memel, Dantzic, Riga, Norway, Prussian, and Russian, and comes under the forms of *baulk* and *deal timber*.

Baulk timber.

Baulk timber consists of the largest square bars which can be cut from the trunks of trees, being generally from eight to sixteen inches square, and sometimes extending to sixty feet in length or more. American baulk timber is of much larger growth than European, being from two feet to two feet six inches square, and in length from twenty-five to fifty feet, or even more.

Deals.

Their dimensions.

Deals are rectangular bars from two and a half to three inches in thickness, and are also imported from America as well as from the North of Europe. European deals are from ten to twenty feet in length, and from eight to eleven inches in breadth, and American deals are from ten to twelve feet in length, and from nine to eleven inches in breadth. The colour of timber is either red inclining to yellow, or white, and is therefore called yellow and white fir accordingly, or sometimes red and white fir.

The fir timber which is the most esteemed in this Country is imported from Memel, Riga, and Dantzic. Norway fir also is much used for the smaller timbers of a building, and is extremely durable when exposed to the air or kept under ground. Red and white pine are imported from America.

Use of deals in building.

Deals are either white or yellow according to the timber from which they are cut. The best European deals are from Christiana. White deals are also imported from America. Deals are mostly used in joinery. Yellow deal is considerably harder than white deal, and being saturated with turpentine is better adapted for enduring the weather. White deal, from its being less liable to shrink than yellow, is proper for panelling and the finishing of bed-chambers, but is not capable of enduring the weather. The American yellow pine, from being straight grained and uniform in its texture, is excellent for mouldings, and is often used for panels; the white deal of America is very tough and strong, but none of the American firs are durable, and in close places are subject to the dry rot.

Use of oak.

Of home growth wood, oak is the only kind which is very useful in Carpentry. Oak in logs is imported from Holland, Prussia, and other parts of Germany, as also from Russia. Oak thus imported is called *wainscot*, and having a fine grain, and being generally free from knots, and more easily wrought than our own oak, is employed in floors, doors, windows, and the finishings of principal apartments.

Wainscot.

Deals are divided into thin, rectangular bars of the

Various kinds of deals.

same length and breadth as the deals from which they are cut by means of the pit-saw. Bars thus cut from two to seven inches in breadth, and from half an inch to two inches in thickness, are called *battens*. Bars from seven inches to any greater breadth, and from half an inch to two inches in thickness, are called *boards*, and all boards above nine inches in breadth are called *planks*. Bars are sometimes so cut that their right section is a quadrilateral or four-sided figure, of which two opposite sides are not only unequal, but the greatest is very small compared to either of the other two; such boards are called *feather-edged boards*, and are of the same breadth and thickness as those which are rectangular. There are other names belonging to deal timber when cut into boards, as half-inch, three-quarter inch, inch, &c. to two-inch deal. *Whole deal boards* are those which are one inch and a quarter thick. *Slit deal* are boards made by dividing a three-inch deal by five cuts of the pit-saw into six boards; thinner boards are called *veneers*.

When deals or other timber bars are divided into boards of the same breadth and length by means of the pit-saw, the surfaces of these boards are very liable to change in various parts, from a plane surface, as was intended, to various curved forms.

Kinds of wood in respect of quality.

Though bars and boards may be selected of a texture apparently uniform, the far greater number contain knots at the points in which the branches begin to issue from the tree, and these knots are attended with a coiling of the fibres round each; the wood of such a bar or board is called *curling* stuff. The term *stuff* is a very common expression with workmen for any material they may have to use as timber, &c. *Clean stuff* is that which is without knots or sapwood. *Free stuff* is that which is clean, and works in the operation of planing without tearing. *Frowy stuff* is a piece of timber or board of a soft texture, and with brittle fibres.

Shrinking of timber.

Timber after having been cut into various rectangular bars, when exposed to the weather will contract in breadth and thickness; but after a certain time, in a uniform temperature, will cease to become less. This contraction arises from the expulsion of the natural sap, and may be promoted by various means; but whether by Nature or Art, a piece of wood or timber having undergone this change is said to be *seasoned*.

The surfaces of all rectangular bars, though they may have remained correct after having been cut or divided, will be very liable to change in seasoning, so as to become concave and convex in various directions, and thin bars will be more liable to this change than those which are thicker.

When any face of a board or piece of timber is a quadrilateral, and when the surface is concave between two opposite corners and convex between the other two, the surface is said to *wind*, or to be *winding*.

Timber liable to warp or wind.

Such a form of surface is also said to *warp*, and the effect is called *warping*. Some woods are more liable to warp than others; thus American white deal is more liable to warp than that from the North of Europe. The warping of timber is occasioned by some of the fibres being in a state of tension, and others in a state of compression; circumstances which arise from the unequal exposure of timber in a growing state to the weather, and from knots and other irregularities.

The effect of seasoning timber.

Timber, in the act of seasoning, is not only subject to bend and warp, but is also liable to rend in various places. Timber which is thus partially split is said to be *shaken*. This disagreeable effect may be often prevented before the timber is used by being careful in the seasoning; and after it has been put to use, by painting the exposed surface immediately with two or more coats of oil paint.

A piece of timber properly seasoned is not liable to warp, or to change its magnitude in any considerable degree; and besides, its stiffness and hardness will be greatly increased. In this state it is best adapted to every purpose of building. Timber is contracted in breadth or in thickness in passing through the various degrees of change from moist or dry weather, and expanded in passing through the contrary state; but whatever variation takes place in a direction perpendicular to the fibres, the change of length in the direction of the fibres themselves will be almost imperceptible.

Compression of timber.

A piece of timber may be compressed in a direction perpendicular to the fibres; so that after the compressing forces are taken away, it will be greatly reduced in breadth or in thickness, but very much increased in hardness. No compressing forces, however, can be employed to shorten its extension in the direction of the fibres, in any sensible degree, without crushing or crippling the fibres.

Use of glue in joining together.

Another valuable property which wood possesses, is that two or more pieces may be connected together by an intermediate substance called glue. The two pieces thus connected will acquire a degree of adhesion equal to that of the wood itself in separating the fibres longitudinally from each other; and thus two or more boards may be joined edgeways, so as to form a surface to any extent of breadth which may be required. It must, however, be observed, that whenever two or more pieces of wood are glued together, they must not be exposed to a damp situation; and therefore must always be under cover to protect them from the influence of the atmosphere.* No boarding, however, of this description can be made so that one of its surfaces may fill a permanent inclosure, or surrounding border, or frame, from the shrinking of the timber in its transverse direction; and if a board thus glued together be fastened along its two longitudinal edges, (supposing the surface a rectangle,) it will be liable to split, and the exposed surface will be liable to change from its first position.

A series of boards placed together, so that the edges may join each other, and that a right line, or straight edge, stretched along the whole may coincide with the surface of any board thus joining, is called a *plane of boarding*; or, more generally, *common boarding*.

Use of nails in joining timber.

A most useful property of timber is, that a spike or nail of considerable thickness may be driven into a piece of wood of sufficient substance to a considerable depth, or even through its whole breadth, without splitting it, and without having any other effect than merely compressing the fibres on each side: and the adhesion of the nail or spike thus driven is so strong as to require very great power to extract it.

Timber exposed to the action of the atmosphere is subject to speedy decay by rotting; the period of its duration may, however, be greatly prolonged by painting its exposed surface with two or more coats of oil paint; but, previously to the operation of painting, if the surface be covered with two or more coats of linseed oil, until the wood become saturated to a considerable depth from the surface, this last process will greatly extend its period of duration.

---

* Unless the glue be made in the following manner it will not endure the weather. Mix with the glue white lead and linseed oil in a leaden pot, which is considered the best for the purpose, and in this vessel boil them a sufficient time; and the compound of these materials thus prepared will be found to answer the purposes, applying it in the same manner as before described with common glue.

Boards may be bent upon a curved surface, or upon several bars of wood, of which the edges are arranged in a curved surface by means of nails.

How timber is bent.

Timber bars may also be bent by being brought into a pliable state either by boiling or steaming; and in this state, if sufficiently softened by the operation, they may be bent, so that the linear edges may form plane curves, to a certain degree of curvature; but, however pliable the state to which the timber may be reduced, it is very difficult to bend a bar so that the linear edges may form curves of *double curvature*. After a piece of timber has been thus bent, and become cold and sufficiently dry, if it be taken off the mould, the curvature will be lessened in a small degree; and if the ends of the piece are not confined, it will still continue to unbend, as it endeavours to regain its rectilinear direction.

Timber stronger and cheaper than stone.

The solid materials fitted for building are stone, brick, metals, and timber. In comparing two square rectangular bars of equal length and of equal breadth upon each side, the one bar being of stone and the other of timber, (we shall say of yellow deal,) then, whether these bars be employed to resist the force of tension or compression, or a force transversely applied, it will be found that the timber bar is the strongest; hence, yellow fir is preferable to stone when used either as a tie or a straining bar, or to sustain a weight or pressure acting transversely. Timber is lighter than stone, and therefore throws less stress upon its bearing supports. Moreover, bars of timber can be procured in lengths vastly greater than that of stone, and therefore in this respect more accommodating to a great extent of bearing; and not only so, but to form bars of stone would be much more expensive than those made of timber. Timber is not only preferable to stone in resisting pressure, but also in resisting percussion. The use of brick in resisting a transverse strain, or the force of extension, is altogether out of the question. As to metals, iron is the strongest of those that are sufficiently cheap for common use. Iron bars are stronger than wooden bars of the same scantlings in any of three modes of applying powers; but yellow fir is stronger and cheaper than iron, weight for weight; on this account, therefore, it is more economical, and consequently more generally employed.

Iron has, however, some properties which timber does not possess; *viz*. that it can be easily bent into curves of every degree of curvature, or even formed into the most acute angles, without the strength being sensibly impaired; but straight-grained timber can be bent only into a small curvature; and in no case can a single piece of such timber be formed into an angle without weakening the piece by cutting it across the fibres; neither can two bars of straight-grained timber be joined so as to form an angle, which will not be much weaker at the joint than in any other section of each of the parts.

Use of iron in building.

Thus it is that iron becomes a useful auxiliary in securing the joints of timber framings either in the form of straps, bolts, spikes, or nails, or by any combination of these. Iron is, therefore, a most essential material in the constructive parts of Carpentry.

Comparative uses of timber and iron.

Though timber is more generally employed in this Country than iron, owing to the cheapness and the great ease by which it is wrought, the adoption of the one or the other of these materials will depend upon the purpose to which it is to be employed. If the object be to form such a construction as shall be proof against fire, as also to be of small dimensions, or of small thickness, or even of the same thickness when great strength is necessary, and when the weight is not an object, iron must in this case be preferable to wood. In the introduction of iron, however, it will be of some advantage to remember the following observations.

Expansion and contraction of iron by heat and cold.

All metals are subject to variation from the extremes of heat and cold; for they are expanded by heat and contracted by cold proportionally in all their dimensions. Moreover, iron, when exposed to the action of the atmosphere, is soon brought to a ruinous state by decomposition. These rapid effects of destruction may be greatly retarded by painting the exposed surface several times over with oil paint.

To resist impressions by violence or accidental force, wrought iron is both cheaper and better adapted than any other material. Cast iron, however, is better calculated to resist oxidation than wrought iron; and therefore, for many purposes is preferable, particularly in bending stone work together With respect to timber work wrought iron is preferable to cast iron, used as fastenings, in the form of straps, bolts, nails, &c.

Preliminary observations.

In order to have a complete understanding of the adaptation and applications of different materials to building purposes, particularly that of timber, and of the proper forms into which it may be cut, it will be necessary to describe the figures of buildings as will at the same time be both convenient and cheap, and which, if required, may be susceptible of elegance and decoration.

Most economical forms of building.

It is not only economical that every floor should be level, but a level position is also the most easy for walking upon; and because our position in walking is vertical, the surfaces also of all walls within rooms ought to be vertical, at least to a certain height, in order to occupy the area of the floor to the most advantage; moreover, the laws of gravitation require the surfaces of walls to be vertical. In economical buildings, plane surfaces are easier to execute than any other; hence in this case the figure of every room ought to be that of a right prism, of which one of the ends or bases is the plane of the room, and the other end is the ceiling, and of which the sides are the surfaces of the walls. Hence the plan of every room as regards convenience and economy ought to be a rectilinear figure or polygon, and all the faces of the walls, which are the sides of the prism between the ends, should be rectangles.

When a building consists of two or more rooms, in order to occupy the least space and to use the fewest materials, the walls or partitions between them ought to be equally thick; hence every wall, whether exterior or interior, ought to be comprised between parallel planes.

Among all the figures which may be given of the plan of a room, a rectangle is the most convenient for furniture and accommodation; therefore since every rectilinear figure, of which every two adjacent sides form a right angle, may be wholly divided into rectangles of equal or of various dimensions and proportions, the subordinate rectangles will constitute the plans of the rooms and division walls.

A building upon a rectilinear plan having every two adjacent sides reciprocally perpendicular to each other, forming a right rectangular solid figure, is better adapted for subdivision than one of any other figure, as not only being the least expensive upon the whole, but as every room is more convenient than one of any other figure. For walls which are oblique to one another require more materials at their junction, and are therefore more expensive; and they are not only weaker than those which are at right angles, but they introduce forms which are inconvenient for furniture.

Therefore to execute a building at the least expense, and at the same time to be the most convenient in respect of accommodation and communication, all the dihedral angles of rooms should be right angles; hence all three trehedral angles ought to consist of three plane angles, all which are right angles. Therefore any two distinct surfaces whatever, must either be in the same plane or in parallel planes, or in planes reciprocally perpendicular to each other. Hence any two distinct lines formed at the meeting of these planes must be right lines, which are either in the same right line or in parallel right lines, or in right lines reciprocally perpendicular to each other; moreover, in any such right line and in any plane, the right line will either be in that plane or parallel or perpendicular to it.

Because the plans of all walls and partitions are comprised between parallel lines, and because planes passing along parallel lines are also parallel as well as the lines, the substance of every wall and partition carried upon these planes is comprised between parallel planes. Moreover, as the surface of a floor for walking upon is more convenient and less expensive in a horizontal than in an inclined position, and since in economical buildings every room is the figure of a right prism, of which the floor is one end and the ceiling the other; therefore as the floor is horizontal the ceiling also must be horizontal; and as it is convenient in every story of a building consisting each of two or more rooms, that all the floors of these rooms should be on the same level, therefore the substance of the division between two adjacent rooms, one immediately above the other, is comprised between parallel planes, the upper plane being the floor of the upper room, and the lower plane the ceiling of the lower room; hence the substance of all exterior walls and divisions of rooms ought to be comprised between parallel planes, whether the surfaces are horizontal or vertical; and generally, as all rectangular apertures receding from vertical planes having each two sides perpendicular to the horizon, and consequently the other two parallel, are not only cheaper to form, but the figure is more congenial to the shape of the room than any other; it is for this reason that rectangular apertures are more generally adopted than any other form whatever. All the meeting lines of vertical surfaces, whether external or internal, being right lines perpendicular to the horizon, are much more easily executed than curves, and consequently are cheaper. All the ceilings and floors of buildings, as regards convenience and economy, must be parallel to the horizon. The substance between the apparent surface of the ceiling of one room and the apparent surface of the floor next above is comprised between two parallel planes, as well as the substance of walls and partitions. Moreover, the floors and ceilings of rooms, the soffits of the apertures of doors and windows in economical buildings are parallel to the horizon.

It is therefore from motives of economy and convenience, that the far greater part of buildings are constructed as here described. Hence whenever buildings or rooms are mentioned, though the plan may be of any figure whatever, it will always be considered as a rectangle unless otherwise defined. This is the reason why timbers are generally divided longitudinally into rectangular bars; for if the right section of any timber bar be required of any other figure, it is most convenient to form such a bar from a rectangular one; but bars which require to be of a different figure in their sections will scarcely occur in any part of such building except in the margins or in the several sides of a roof.

All the parts of a habitation which appear to the eye are called *apparent surfaces*. These apparent surfaces ought to be plane figures.

Every material used as a covering, in order to possess sufficient strength and continuity, must have such thickness as is requisite to preserve the apparent face in its due form. This thickness, in the covering of roofs, is the distance between a plane containing the arris lines of the courses, and the plane of arrangement which contain the under faces of the boarding and the edges of the supporting timbers; in partitions and ceilings the thickness of the covering is the thickness of the lath and plaster together, which is equal to the distance between the apparent face of the plaster, and the plane containing the edges of the supporting bars; and in the boarding of floors, the thickness of the covering is the distance between the surface for walking upon and the plane containing the edges of the supporting bars and the lower face of the boarding.

Surfaces to cover hypethral apertures in order to shut the interior, so as to effect the stoppage of rain and inclement weather, as also the rapid discharge of water generated by rain or snow, and at the same time to be both beautiful and cheap, ought to be constructed in inclined planes.

As no apparent surface can exist without substance, we shall call the material, whatever it may be, by the simple name of *covering*, or by the compound names of *covering substance*, or *covering material*, which will always be supposed of uniform thickness.

Every covering will therefore be comprised between two parallel planes. We shall call the plane of this covering opposite the apparent face, the *concealed face* or *invisible face*.

Of Wall Timbers.

All the operations in economical buildings are constructed for the purposes of supporting the apparent coverings, in whatever position or situation they may occur; the materials should therefore be of such strength as will enable them to resist the accidents to which they may be exposed.

Applications of brick and stone.

The exterior walls being carried up between vertical surfaces, will be best constructed with solid and weighty materials, such as stone or brick bedded in mortar, as the more weighty the materials are, the more capable will be the walls of resisting the pressure of heavy winds and tempests, and their position, if they are sufficiently thick, will prevent the possibility of their falling either to the one side or to the other, and thus it will be impossible for them to produce any lateral pressure; but on the contrary they will be able, if sufficiently thick, to resist any proposed lateral pressure whether applied upon the one side or upon the other.

Partition walls are often built with brick or stone bedded in mortar, particularly when it is required that they should contain chimnies. In such cases, where cheapness and the saving of room is required, partitions may be constructed of timber work adapted to support a covering on both sides of lath and plaster. Such a construction of timber becomes necessary whenever the floor under the partition is unsupported from below, except under the vertical extremities of the frame.

Use of timber in building.

Therefore the principal objects to which timber is applied in buildings, are the framings used in supporting the coverings of partitions, floors, ceilings, and roofs.

Lintels, bond timber, and wall plates. Wood bricks.

Timber is also applied in exterior walls; thus long pieces of timber, (*piles*,) and sometimes planking are used in bad foundations; as also for the greater security timber bars (*sleepers*) are laid transversely at short intervals under the foundation, extending about two feet wider. Other timbers (*lintels*) are laid horizontally over the apertures of doors and windows to support the superincumbent part of the wall. Other timber bars (*bond* or *chain timber*) are built into the walls in order to prevent settlements; and others again (*wall plates*) are inserted in order to give a firm support for the timbers of the roof, and those of the floor or floors when such occur in the building; besides these, pieces of timber (*wood bricks* or *plugs*) are built or driven into walls for supporting the timber bars to which the laths for sustaining the plaster is nailed, and for the conveniency of fixing the finishings required in Joinery. Bond timbers, wall plates, lintels, and wood bricks, should always be laid in walls in a horizontal position with two faces parallel and two faces perpendicular to the horizon, and with one of the vertical faces parallel to the faces of the wall. Bond timbers, in order to be the most durable, should be made of oak, and they ought to be placed in the middle of the thickness of the wall, and not to have either of their two vertical faces in the interior face of the wall, as the shrinking or decay of the timber will greatly weaken the substance of masonry or brickwork, and thus will hasten the destruction of the fabric. Bonds made of cast-iron, with one face flush with the interior face of the wall, and with holes at regular intervals for plugs, would not only be proof against fire, but would add greatly to the strength of the wall. After the stone lintel has been laid over the aperture of a window or door, the remainder of the breadth between it and the inside of the wall may be covered with wooden lintels, in order to save the expense of iron or of a stone arch. The thickness of wooden lintels ought to be as many inches as the bearing distance is in feet.

Timbers inserted in a wall, or in walls for supporting the ends of the horizontal timbers in a roof, or those for supporting the ends of the timbers in a floor, are called *wall plates*, and are employed in order to distribute the pressures of the timbers which they support upon the walls. Without wall plates the masonry or brickwork would be liable to be crushed under the ends of the timbers, which would act partially, and thus dislocate the parts underneath; one of the vertical faces of every wall plate should be flush with the interior surface. The sizes of wall plates will greatly depend upon the thickness of the walls, and the weight of the timbers which they have to sustain. In thick partition walls of stone or brick, the wall plates should be double upon each such wall, and their upper faces as well as their lower faces ought to be level.

The greatest care, however, must be taken not to place any timber inserted in a wall, in whatever office that timber is to serve, nearer to a flue than nine inches; and if it be necessary that timbers should be placed, so that they would fall upon flues, the ends must be cut off, and cast-iron ends must be fixed to the timbers, and these must be supported upon cast-iron wall plates or templates.*

Construction of Floors.

When any room in the basement story of a building is intended for living in, a boarded floor will be found the most comfortable; and as boards cannot lie solid without being fixed to some material or other, and as timber is the most convenient for the fixing of timber, a row of timber supporting bars, laid upon dwarf walls, or upon props of stone or brick piers, is generally employed for the fixing of the boarding; the supporting bars for this covering are called *ground joists*.

Naked flooring

In a house which consists of two or more stories, the timber work which is necessary for supporting the covering of the floors for walking upon or the coverings of the floors and ceilings together, is called *naked flooring*, and by some writers *carcase flooring*. To accommodate rooms of various dimensions, naked flooring consists of two different kinds.

Single joist floor

One species of naked flooring may be constructed with a row of timber bars, which at once supports the floor for walking upon and the ceiling of the room below. This description of naked flooring, which is the most simple of any, is called a *single joist floor*.

Beam filling

When the building has been *carried up*† nearly to the clear height of the story, the inside of the walls must be levelled, so that when the wall plates come to be laid, and the ends of the joists upon the wall plates, as also the ceiling finished, and the floor below is completed for walking upon, the clear height of the story may be equal to that which it was intended to be; then if another story be intended, after having laid the wall plates, and the joists upon the wall plates, the walls must be again carried up, by previously building upon the wall plates in the interval between the ends of the joists, so as to fill up every cavity to the level of the top of the joists. This operation is called *beam filling*.

Cockings.

Another mode of constructing naked flooring is to support the supporting timbers by another stronger row of timber bars laid upon the wall plates. The timber bars of the row thus laid, are so notched upon the wall plates as to prevent the timbers being drawn off the top of the wall plates, and therefore from being drawn out of the walls, by pulling the timbers in a direction of their length, without either tearing the ends of the timbers or the wall plates. These notchings, as well as the operation of framing them, are called *cockings*.

Binding.

The building is generally roofed in before the supporting bars are laid, and when they are laid their ends do not penetrate or enter into the thickness of the walls, as the row of timbers upon which they are laid, but only abut upon the interior face of each opposite wall. The supporting bars and the *bearing timbers* which support them are notched into each other, so that the supporting and bearing bars may be comprised between two horizontal planes, of which the distance is less than the sum of the depths of one of the bearing timbers and one of the supporting bars. Each of these rows of timbers is called *joists;* the lower row of bars, or bearing timbers, is called *binding joists;* and the upper and bridging joists.

---

* For an explanation of this term, see *postea*, p. 235.

† Walls are said to be *carried up* when they are built to any required height. The terms *bring up* and *brought up* are also used for *building up* and *built up*.

row, or supporting bars of the covering, is called *bridging joists*; moreover, the construction of naked flooring is called a *bridged floor*.

In order that the timbers may have equal bearings, and that they may have the utmost advantage in point of strength, and in economy, materials, and workmanship, as also to render them convenient for joining one another, and for fixing the coverings, two faces of every two joists, whether in the upper or lower row, ought to be parallel to either face of two opposite walls or sides of the room, and all the intervals of the binding, as well as those of the bridging joists, should be equal to each other. In substantial works, the supporting bars, whether in a bridge floor or in a single joist floor, ought not to be more than one foot from centre to centre, that, is in every two adjacent joists the distance from in to out ought not to exceed one foot.

It is obvious that in bridged, naked flooring, the transverse strength of the bridging joists by a force acting in the middle of one of its bearing distances, (that is, between two binding joists,) should not be greater than the strength of a bridging joist and the binding joists, supporting it by a transverse force acting in the middle of the area comprised by the four sides of the room. Hence it is evident, that the binding joists ought to be placed at much greater intervals from each other than the bridging joists. Therefore, owing to the great distance between the intervals of the bridging joists, the lath upon which the plaster of the ceiling is laid being very thin, cannot be attached to the under edges of the binding joists, without being too weak for sustaining the plaster. Therefore, to render the laths of sufficient strength, another series of supporting bars for the lath and plaster may be introduced and placed at such intervals as will render the bearing distances sufficiently short to give the degree of strength required. The timbers thus introduced are called *ceiling joists*. The ceiling joists are either nailed upon the binding joists, crossing two or more, or even extending from wall to wall in one length; and to save room they may be notched, so as to make shorter nails answer the purpose of fixing them to the binding joists, which ought not to be notched, as they have to support the two coverings; *viz.* the boarding for walking upon, and the ceiling of the room below; or instead of extending the ceiling joists across the timbers, they are sometimes let into the binding joists so as to be very nearly flush with the lower edges of the binding joists, and thus the thickness of the binding joists and bridging joists may be comprised between two horizontal planes, of which the distance is very little more than the depth of a binding joist. This mode of fixing the ceiling joist is not so strong as extending them over the binding joists, which, however, is much more expensive.

Thus in a bridge floor we have a compound frame, consisting of three rows of timber bars, all called by the general name of joists, of which each row of supporting bars or joists is supported by the binding joists, which constitute the middle row.

These rows in economical buildings have all their vertical surfaces in planes which are either parallel or at right angles to each other, as well as to the interior faces of the walls of the building.

Sometimes, however, the walls are at so great a distance from each other, as to cause the entire distance between two horizontal planes, which will just comprise the thickness of the naked flooring, to be so great, as to render the binding joists too weak. Therefore, in order to furnish shorter bearing distances for the binding joists, one or more rectangular timber bars, of the largest scantling which can be found, are introduced instead of walls for supporting the ends of the binding joists, and are called *girders*. The girder or girders ought to divide the length of the room into two or more equal intervals, and their surfaces ought always to be comprised between the parallel planes which comprise the naked flooring.

Girders.

Bay of joisting.

Case and tail bays.

The part of a bridged floor comprised between two adjacent girders, or between a girder and the wall, in clear space is called a *bay of joisting*, that in the clear of two girders is called a *case bay*; and that in the clear between a girder and the wall is called a *tail bay*. Moreover, when there are no girders, the bridging and ceiling joists between the binding joists in the clear, or between a binding joist and the wall in the clear, are called a *bay of joisting*. A bay of joisting between two binding joists is called a *case bay*, and that between a binding joist and the wall is called a *tail bay*.

Templates.

Girders are supported by short pieces of timber placed under their ends, which are inserted in the wall. These short pieces of timber, called *templates*, ought to be of sufficient length, to distribute the pressure of the girders to a considerable extent along the wall or walls, because the entire weight of the floor will press upon the templates.

We shall call all the timbers which derive their support immediately from the wall, whether they are placed upon wall plates or upon templates, by the name of *bearing timbers*. All bearing timbers ought to be supported at their extremities upon the two walls, which are in the direction of the length of the room; hence in a single joist-floor the length of the joists should be laid in the breadth of the room, and thus the direction of the boarding will extend in the length: in a bridge floor (sometimes called a *double floor*) which has no girder, the binding are the bearing timbers, therefore the direction of the binding joists ought to extend in the breadth of the room, as also the boards which form the covering or floor for walking upon; moreover, in a bridged floor with girders, the girders are the bearing timbers; hence their direction ought to extend in the breadth of the room, as well as the bridging joists; therefore, the binding joist and boarding will extend in the length.

It is obvious that when the plane of a room is square, the strength of the timbers can never be affected, whether they are placed parallel to one side of the room or to the other; hence in such a case as this, and when there are more than two or more rooms upon a floor, the choice of the direction of the timbers will be influenced by the direction of the timbers in the other floors, or by the direction of the boarding. When the direction of bearing timbers extends over two or more rooms, they will be much stronger if they extend in single lengths over both openings.

Wood will resist either by compression or extension, therefore in a building consisting of two or more stories, the walls will be greatly strengthened by the timbers, and will consequently be more capable to resist the pressure of heavy winds or other accidental forces; hence, with such assistance, the walls will not require to be so thick as independent walls of the same height. As a further contribution towards the strength of the building, the wall plates in very substantial buildings are often fixed to each other at the angles, and the two wall plates, which are thus joined, are again joined by a third bar of timber fixed at each end to each of the other two, at equal distances from the joining of the two wall plates; the three timbers thus joined, encloses a space in the form of a right-angled triangle, the two sides which are perpendicular to each other being equal. The piece of timber which is opposite the right angle is called a *diagonal tie*, or *angle brace*.

Diagonal tie or angle brace.

Floors are generally interrupted by one or more circumstances: every comfortable room must have a fireplace, and whenever a building consists of more than one story, a stair will be necessary to pass from the one to the other. For the safety of the building, in order to prevent its being liable to burning, no joist nor girder ought to be placed near to a fire-place, nor to enter any wall containing flues opposite to the ends of the timbers. But from whatever circumstance bearing timbers are interrupted, instead of inserting the ends of the timbers they are generally cut off, and the ends thus cut off are framed or fixed to a timber bar, and the ends of the timber bar are fixed to the two adjacent joists, which remain uncut. The timber bar which sustains the ends of the joists is called a *trimmer*, and the two joists which support the trimmer are called *trimming joists*. When the trimmer is opposite to flues it is called a *tail trimmer*, if opposite to a fire-place it is called a *hearth trimmer*, and if to make way for a stair it is called a *stair trimmer*, which forms the margin of the landing. Tail trimmers are generally brought close to the wall; but hearth trimmers, on account of the marble slab which is necessary to protect the fire from the timber work, are fixed at some distance from the surface of the adjacent wall.

Various kinds of trimmers.

As the slab which forms the hearth requires a support, the space under the hearth between the trimmer and the wall must be filled with something in order to support the slab; and, since nothing is stronger than an arch, a brick arch is generally thrown over between these extremities as abutments, which are the hearth trimmer and the wall, at such a distance from the apparent surface of the boarding as is sufficient to receive the slab, generally constructed of stone or marble.

The arch thus thrown also is called a *trimmer* by the bricklayer, but to distinguish it from other trimmers, it is called a *brick trimmer*.

The mould upon which the arch is formed is called the centre of the trimmer. It is obvious that the brick trimmer must be comprised between two parallel planes, of which the higher is below the level of the floor, and the lower above the surface of the ceiling.

Scantlings.

In the construction of naked flooring and roofing the small timbers which are used are called by the general name of scantlings, though, perhaps, not with good reason; as this term has been appropriated to the dimensions of breadth and thickness of a rectangular bar, and in regard to squared stones the term is applied to the three dimensions of length, breadth, and thickness.

In the construction of the timber works of floors and ceilings, the arrises of the timber ought always to have a horizontal position and to be perpendicular to the two opposite walls, and consequently parallel to the other two opposite walls.[*]

Horizontal framings are used in roofs as well as in floors, to prevent the action of the oblique timbers from thrusting out the walls, They also serve to support the timbers to which the ceiling of the room below is attached; such a construction is called a *ceiling floor*.

Construction of Partitions.

Every construction of partitions where the bearing is solid below the framing, ought to be filled with timber bars, called *quarterings*, of which every timber has each of its four faces perpendicular to the horizon, and of which the interval between every two adjacent timbers is equal. But when the floor under the partition is unsupported, as the partition ought not to lay any stress upon the floor, it ought to be supported only at the extremities of the under edge. Now if the partition be filled with timbers, as has been described, the whole weight of these timbers will press upon the unsupported part of the floor. To prevent the strain which they would give, and to make the partition capable of supporting the floor above, and even the floor below, if necessary, two oblique timbers must be fixed in such a manner that the lower end of one must rest upon the one supported extremity, and the lower end of the other upon the other supported extremity. The upper extremities may either meet each other, or meet an intermediate post, or they may meet two intermediate posts with an interval between, in such a manner that each oblique timber may meet the nearest post; between the two posts, opposite to the places where the oblique timbers join, another piece of timber bar must be inserted in the interval. Whether there are two posts with an interval, or only one post, two timbers will meet every post; and, including the post, three timber bars will therefore meet each other. To prevent this timber from moving, the three timbers must be secured to each other at every junction of three timbers: the triple junction of the timbers is called a *joggle*, the oblique timbers are called *braces*, and the intermediate piece is called an *intertie*. Hence, when only one post is used there are three joggles, and when two posts are used there are four joggles; in each case the joggles at the lower ends of the braces are included. The posts, when the partition contains a door, are those which form the sides or jambs of the door, and the intertie is the head of the door. When there is no doorway, the timber along the floor becomes a tie. The whole of the partition is included within a rectangular frame; the post or posts must meet the horizontal sides of the frame.

The interruption of doors in partitions frequently occasions an irregularity in the position of the braces, and, in many cases, so much so as to render their effect insufficient. But since the door is generally much lower than the height of the story, the head of the doorway is extended so as to meet the upright timbers at each extremity of the partition, and thus the rectangular frame will be divided into three rectangular compartments when the partition contains one door, and into four rectangular compartments when the partition contains two doors; hence the upper compartment, which extends the whole length of the partition, may be framed in the very same manner as the whole would have been when it contained no door, or when it contained one door in the middle; and this framing might even be made of sufficient strength to support the floor above, and the timbers below adjacent to the door or doorways without bracing any of the lower compartments: very frequently, however, the lower compartments are braced as well as that above the door or doorways.

---

[*] Bridge floors have been long in use, and had always been considered as the best in order to support the covering and ceiling over a large area, until Professor Robinson caused two models of naked flooring to be made, one being a single-joist floor, and the other a bridged floor, each containing the same quantity of timber, and covering equal areas. These models were each loaded uniformly with small shot until they were broken; the strongest was that constructed of single joist. The same experiment has been recently tried, and the result of Professor Robinson has been verified by Professor Barlow, of the Royal Military Academy at Woolwich. It has, however, been argued in favour of the compound framing, though not in such a manner as to decide the fact, that its use is better calculated to preserve the ceiling from cracking than a single-joist floor with deep joists.

Use of parabolic arches in partitions.

As the timbers which support the lath and plastering are most advantageously arranged when their faces are in planes perpendicular to the horizon, and when their intervals are equal, and as these vertical timbers must rest upon the braces, which would therefore be bent by the pressure, and consequently would either have their effect diminished or entirely destroyed; in order to render them as effectual as they were intended, parabolic arches, described so as to answer to the obliquity of the braces and intertie, are recommended; these arches ought to be double, and opposite to each other, and if they are made of iron, they may either be used as a tie or in a state of being compressed.

The upright quartering for the fixings of the lath being fixed to two such arches will effectually prevent them from descending by their weights, and thus the whole stress will be thrown upon the joggles; the braces and intertie, when there are two posts, will be in a state of compression, but the weight of the timbers upon the arches will lessen the degree of compression upon the straining pieces.

Quarter partitions.

Partitions constructed of timber bars to be lathed and plastered are called *quarter partitions.*

Brick nogging partition.

There is yet another species of partition constructed with timber posts placed at equal intervals, and filled with brickwork between the adjacent posts, which are called quarters; the quarters are placed at eighteen or twenty-seven inches in the clear, and to strengthen the brickwork, horizontal pieces of timber extend between the quarters over every five or six courses of brick. A partition thus constructed, partly with brick and partly with timber, is called a *brick nogging partition*, and the work done in this manner is called *brick nogging*. The horizontal pieces between the quarters are called *nogging pieces.*

Brick nogging partitions ought always to be constructed upon a solid foundation, and, consequently, ought never to be used but in ground or basement stories. The quarters ought always to be three-quarters of an inch thicker than the brick, so that half the difference, or three-eighths of an inch, ought to project before each face exhibited by the brickwork, in order to allow for the irregularities of the surface of the lath, occasioned in the splitting by the sinuosities of the fibres in taking curve directions round the knots.

Of the Various Kinds of Roofs.

Gable ended roof.

A *common roof* is that which has only two apparent sides, which meet each other in the ridge, and which rest upon opposite walls, which, in isolated houses, are generally the two opposite walls that have the least interval. This roof is called a *gable ended roof.*

Common hip roof.

A *common hip roof* is that which has only one apparent face adjacent to each of the four walls, and the two apparent faces which rise from the two opposite walls, which have the least interval, meet each in the ridge.

As the meeting plane of a hip roof generally bisects the dihedral angle formed by the external faces of two walls which meet each other, every two planes which meet have the same inclination to the horizon, and the right section of a common hip roof between the two most remote walls is a trapezium; but if the dimensions of the aperture to be covered are equal, all the four faces of the roof will meet in a point, and each of the right sections through this point will be an isosceles triangle.

Truncated roof.

A *truncated roof* is that which is flat upon the top, and may either be of the simple prismatic form or hipped. When it is not hipped it is called a *simple truncated roof*, and when it is hipped it is called a *truncated hipped roof.* A truncated roof is also called a *terrace roof* or *cut roof.* A truncated roof has its right section in the form of a trapezium, with two parallel sides, and the two diagonals equal; the side which is parallel to the base is not absolutely a right line, but is raised in the middle to an obtuse angle for the purpose of discharging the water. The top, which is nearly horizontal, ought to be covered with lead.

Curb roof.

A *curb roof* is that which has two sloping faces upon each side; when it consists only of a simple prism it is called a *common curb roof*, and when it is hipped it is called a *curb hip roof.* A curb roof is also called a *mansarde roof.*

As the roof of a rectangular building may consist of the intersection of two or more prisms, as has been described, these intersections may be either external or internal, that is to say, the dihedral angles of their planes may either advance or retreat, and, accordingly, are called by the French *salient* or *re-entrant* angles; hence when the dihedral angles of the adjacent sides of a roof are *salient*, every two of such which meet each other will form a hip, which has already been described; but when the dihedral angles are *re-entrant*, they form what are called *valleys.* A roof having a valley is called a *valley roof.*

Hip and valley roof.

A roof which has both a hip and valley is called a *hip and valley roof.**

The roofs of buildings in which the faces of the walls terminate in horizontal right lines are called *straight roofs*, in order to be distinguished from curved roofs. Curved roofs are generally circular and isolated. We may, however, have both straight and curved roofs independent of each other, or intersecting each other.

Dripping eaves.

Roofs either cover the tops of the exterior walls from which they spring entirely, or only partially; when a straight roof covers the top of the wall, the inclined surfaces are prolonged before the face of the wall several inches, or even feet; such a roof is said to have *dripping eaves*, and the parts thus prolonged are called the *skirts* of the roof; in such a roof the water is supposed to drop from the margins of the eaves upon the ground without being stopped in the way.†

---

* When the plan of a building is curved, the walls are also curved surfaces, and the roof is denominated from the plan of the building, or from the form of the top of the walls; a roof for such a building is called a curved roof. Hence, when the top of the walls from which the roof rises is a circle, the roof is called a *circular roof*, and, if an ellipse, it is called an *elliptic roof*, and so on.

† Such forms of roofs have sometimes troughs placed with a gentle inclination under, but near to the margin of the eaves in order to carry the water into pipes; but the appearance of such appendages is rather unsightly.

Straight Roofs.

Straight roofs of the most agreeable and best construction ought to have a certain number of dihedral angles. Let us conceive, either in a hip roof, or in a hip and valley roof, a bar to be fixed in the intersection of every such angle; and the plane which bisects the dihedral angle to divide the bar into two equal parts, so that two of its faces may be parallel to the bisecting line.

Let us again conceive, at the margin of every face of the roof which joins the wall another bar to be fixed, so that two sides may be parallel to the horizon; these two faces will therefore make an acute angle with the plane of arrangement, or with the apparent face of the covering; and suppose all these bars to meet each other, so as to form a complete frame surrounding the aperture to be covered; also, let the upper edges of the bars of every such frame be in the plane of the supporting bars of the covering, (that is, their plane of arrangement,) so as to allow for the proper thickness of covering and boarding. If any particular bar is required to project above the apparent face of the covering, draw a right line on the inner face of such a bar which will mark the intersection of the surface of the plane of arrangement.

Ridge piece.

Hip rafter.

Wall plate.

The bar in the dihedral angle, of which the line of meeting of its two faces is parallel to the base of the roof, is called the *ridge piece;* and each of the inclined bars in the meeting of every two adjacent inclined faces, which form a salient angle, is called a *hip rafter;* and the timber in every face which joins the wall is called a *wall plate.*

Thus every apparent face of the roof of an economical building will have its enclosure in the form of some of the diagrams, Plate, Nos. 1, 2, 3, 4, &c. to 7. No. 1 is the figure of the apparent sides of a gable ended roof; No. 2 that of a gable end and a hip; No. 3 that of a gable end and a valley; No. 4 that of a hip and valley; No. 5 that of two hips; and No. 6 that of two valleys. The quadrilateral diagrams, Nos. 1, 2, 3, 4, 5, 6, all belong to the longest sides of the roof, and No. 7 to the end of a hip roof.

Here, in this diagram, each timber bar adjacent to each line, or side, is called by the general name of a *bordering piece;* the bordering pieces being joined at the angles will form a triangular or quadrangular form, according as the aperture consists of three or four sides. The frame thus enclosing an open area is called the *surrounding frame.*

In the seven diagrams here referred to, the side B C is supposed to be the skirt next to the wall, and A D that adjacent to the ridge.

Fig. 8 exhibits the plan of a gable ended roof, figures 9 and 10 plans of hip roofs; that of fig. 9 being square, and that of fig. 10 oblong.

Hip roofs, &c.

Fig. 11 is the plan of a hip and valley roof, or what is called, in reference to the plan, an ell roof, being in form of the letter L; and fig. 12 is the plan of a hip and valley roof in the form of the letter T.*

All the supporting timbers of every inclined covering of a roof ought each to be perpendicular to the wall plate, and to have two faces perpendicular to the horizon, and a face in the plane of arrangement. All the intervals between every two adjacent rafters ought to be equal to one another; and the breadth of every interval between the frame and the adjacent supporting bar ought not to exceed the breadth of the interval which is common to the supporting bars. Moreover, every supporting bar ought to be fixed at each extremity to opposite parts of the skirting frame.

Rafters.

Jack rafters.

Hence, if the frame of the apparent face to be covered belong to a hip roof, or to a hip and valley roof, those rafters only can be of equal lengths, which meet a ridge in the summit of the roof and the plate at the bottom; therefore, in the triangular parts, the supporting bars must be shorter and shorter. The supporting bars are generally called *rafters;* and those which are of unequal lengths, and all shorter than the rafters which extend between the plate and the ridge piece, are called *jack rafters.*

But, it is clear, that the longer the rafters are, the greater ought the scantlings to be; therefore their depth, or their thickness, or both their cross dimensions ought to be increased as their length is greater: for if all the rafters were of the same scantling, their strength would be very nearly in a reciprocal ratio of their length. Now, instead of increasing the rafters in thickness, or in depth, or in both these dimensions of breadth and thickness, it is a general practice with builders to make the rafters nearly of the same scantlings for all buildings; and therefore, when they are so long as not to be able to support themselves and the covering without sagging or breaking, it becomes necessary to support every rafter at one or more intermediate points, and thus to divide its length into two or more equal parts.

Purlins.

For the purpose of giving the rafters a sufficient support, it is not only convenient, but economical, to place one or more horizontal rectangular bars, called *purlins,* so that each extremity of every purlin may be fixed to the opposite parts of the bordering frame; and that one of the faces of every purlin, and the lower edges of all the rafters comprised in the length of the purlin, may be all in one plane; and, lastly, that all the intervals between the plate and the ridge may be equal, the number of intervals being one more than the number of purlins.

When the roof only covers the top of the walls in part, the front of the walls may be carried up to any required height above the level of the roof, and a construction of wood, in the form of a trough, is covered with thin sheets of metal, generally lead, for the purpose of carrying off the water into pipes, which may either be concealed or exposed, as the circumstance of the building may require. In such constructions the water-ways are entirely concealed, and sometimes the roof itself, by the walls; the wall thus carried up is reduced in its thickness in order to make room for these water-ways, which are called *gutters,* and such roofs are sometimes also called *gutter roofs;* the part of the wall thus carried up is called a *parapet.*

Gutters are not only placed along the horizontal margins of roofs, but are also made in the valleys of return roofs. When the bottom and side of the boarding of the gutters are supported by short pieces of timber, the gutters are called *bridged gutters.*

Gutters should be made sufficiently wide for a person to walk along them with ease when repairs are needed, and they ought to have a sufficient descent that water may run freely along them; but, instead of making one continued descent, it would be more convenient and less expensive to make two wherever circumstances will admit; and the nearer these descents can be made of the same length the less height will be required for the fall of water; because, when long gutters are made in one descent, as the rise upon the whole must be proportional to the length of run, the distance which they cover the roof must be proportional; or, otherwise, if the breadth of the gutter be confined within parallel limits, the depth must be very great to allow for the proper fall of the water.

[*] It is evident that, in hip roofs, the plane which bisects every dihedral angle will be perpendicular to the horizon: therefore, two faces of every hip rafter, two faces of every valley rafter, and two faces of every ridge piece, ought to be perpendicular to the horizon

Therefore every rafter in that length will be supported by one point of the purlin, and at as many equidistant points as there are purlins in the length of that rafter, making the intervals one more than the number of purlins.

Here the same observations may be made on purlins as have been offered on rafters; *viz.* that it is customary with builders to make the purlins for all buildings nearly of the same scantling, whatever may be their length. Hence, there is only one necessary length between one prop and another that will sustain the rafters and the covering to the best advantage; therefore, if they have any longer bearing than that which would be just necessary between their extremities, that bearing ought to be divided into two or more equal bearing distances. This may be done by placing a sufficient number of other oblique bars in the same direction as the rafters, so that all the upper edges of these timbers, and the under edges of the purlins, may be in one plane; and that the two ends of the bar or bars thus introduced, may be supported, and of such length as to contribute to the support of all the purlins.

Principal rafters.

Common rafters.

The bars for supporting the purlins are called *principal rafters*, and the rafters supported by the purlins are called, by way of distinction, *common rafters*. Again, let it be supposed that the principal rafters are in their turn supported opposite to every purlin, as well as at the two extremities. For this purpose, let as many beams be extended across the building as the principal rafters are in number, and let these beams be supported upon wall plates; *viz.* one plate upon each of the opposite walls in the same manner as the binding joists of a floor were laid upon the wall plates; moreover, let the lower end of every principal rafter be fixed to the end of the beam. Then, if the roof is of the best construction, and be a common hip roof, its right section will be an isosceles triangle; therefore, if on the other side of the roof principal rafters of the same length are supported at their lower extremities, each upon the opposite end of every beam, and if the two equal sides thus constructed for the opposite faces be made to meet each other in a vertical plane passing through the summit, they will necessarily balance each other. However, if they only lean one upon the other, a very small force will destroy their mutual balance: hence, if they are fixed together in any manner so as to prevent them from sliding upon each other, their balance cannot be easily destroyed by any accidental pressure acting upon either side only.

Thus the supports of the purlins have been reduced to a triangular frame of an isosceles figure, the two opposite principal rafters forming the two equal sides and the beams its base. It is obvious that in this state of the timbers, the principal rafters from their own weight, and from the load which they have to support, are in a state of compression, and therefore the beams are in a state of tension.

Tie beams.

Hence the beams are called *tie beams*, and the whole of the triangular frame, together with the timbers it comprises, in order to support the principal rafters most effectually and sufficiently, is called a *truss*, and the principal rafters among builders are often called *principals*. The lower ends of the common rafters, when the construction of the roof requires principals, are fixed to a bar of timber supported upon the ends of the tie beams. This bar is called a *pole plate*. The whole of the timbers, including the purlins and common rafters between every two adjacent trusses, is called a *bay of roofing*. The whole of the timber work for supporting the covering is called a *carcass roof*.

Pole plate.

The timbers of two skirting frames for supporting the covering of two opposite inclined faces of a hip roof which meet and form the ridge have been described. The two triangular frames in the ends ought to be filled with common rafters supported by the same number of purlins exactly in the same manner as has been explained in respect to the sides of the roof.

In large roofs the construction requires a principal rafter reaching from the middle of the wall plate to the summit, and this is supported below upon a half tie beam, and the feet of the common rafters upon a pole plate is in the two sides which meet and form the ridge.

Whatever may be the form of a straight roof, the timber work for supporting the covering of every inclined aperture ought to be constructed in the manner which has been described. Here, as in naked flooring, the common rafter may be let into the purlins in the same manner as the bridging joists of a floor are let into the binding joists. Hence the entire substance of the rafters and purlins may be comprised between two parallel planes, of which the distance will be less than the sum of the depths of a rafter and purlin. The purlins and principal rafters may also be comprised between two parallel planes, which will be less distant from each other than the sum of the depths of a purlin and a principal rafter.

In roofing, not only horizontal and vertical framings are employed in the construction, but oblique framings also. The oblique framings are those which immediately support the covering.

The vertical framings not only support the oblique framings but the horizontal framings also. The whole of the framings, taken collectively, is called the framing of the roof, and all of them are connected and fixed at the joinings. The timbers belonging to the horizontal frame are disposed similarly to those in the framing of a floor, and the timbers in the vertical frames to those of a partition.

Truncate roofs, &c.

Every truncated or terrace roof ought to have at least two sloping sides, and when such a roof is hipped it ought to have at least three equally inclined faces of which two and two are adjacent, and every adjacent pair of inclined faces form a dihedral angle. Such roofs may also have one or more valleys, according to the figure of the plan. The hips and valleys of such a roof, as well as the apertures of the skirting frame, ought to be constructed in the same manner as those of a common roof, or of a common hip roof, or of a hip and valley roof. The upper extremities of the rafters in each face of the roof rest upon a horizontal bar between the inclined face and the flat on the top of the roof; and the principal rafters instead of meeting, have a beam fixed between the top of every two opposite rafters so as to balance them; and thus every truss will consist of four rectangular bars, *viz.* the tie beam, the two principal rafters, and the top beam which is parallel to the tie beam. The top beam, from its rising in the middle in order to give the boarding and leaden covering a gentle inclination, is called a *camber beam*.

Camber beam.

The four timbers of every truss ought to be comprised between the two vertical planes which contain the vertical surfaces of the tie beam. It is evident that in every such quadrilateral truss frame, the top beam and the two principal rafters are in a state of compression, and the tie beam is in a state of tension. The covering of the aperture on the top, supposing it to be rectangular, may be supported by a row of beams perpendicular to each of the horizontal bars, to the sides of which the ends of the common rafters and the ends of these beams may be fastened. The under edges of the level row of timbers ought to be arranged in the same horizontal plane, but the upper edge or back of every timber extending across the horizontal aperture, is generally cut into a very flat or obtuse angle having the summit in the middle, so that all the summits may be in a right line bisecting the aperture. Each sloping side of the camber beams is boarded over, and the boarding is covered with lead.

In the construction of a curb roof, the lower part being the same in form as a truncated roof, and the upper part the same as a common roof, or a common hip roof, the construction of these parts may be the same as that of common and hip roofs. The horizontal bar between the two inclinations will serve to support the tops of the rafters in the lower inclined face, and the feet of the rafters in the upper inclined face. The beams which in terrace roofs are required to support the boarding, do not require to be cambered in the curb roof, as they only serve the purpose of ceiling joists.

Curb rafters. Curb plates.

The rafters used in the upper part are called *curb rafters*, and the timbers in the angles which divide the two inclinations are called *curb plates*.

On the Trehedral in general.

A trehedral is a solid angle contained under three plane surfaces called faces, every two of which meet each other, and all the three in a point called *the vertex of the trehedral.**

Def. The angle formed on any face by the two edges is called the angle of that face, and the face is said to be obtuse or acute, according as the angle of that face is obtuse or acute.†

Def. If from any point in any one of the three edges of a trehedral two right lines be drawn perpendicular to that edge one upon each adjacent face, the angle contained by these lines is called the dihedral angle, which is less than a right angle; it is also called the inclination of the planes.

Def. If a trehedral, of which the angles of the faces are acute, be cut by a plane perpendicular to one of its edges, the triangular section is called a sectional triangle, and each of the three triangles formed by two edges of the trehedral and a side of the sectional triangle is called a lateral triangle.

Def. The edge to which the cutting plane is perpendicular is called the adjacent edge, and the remaining two edges of the opposite face are called opposite edges.*

On the Right Trehedral.

Def. If two of the faces of a trehedral be perpendicular to one another, the trehedral is called a right-angled trehedral.

Def. The two faces of a right angled trehedral which are perpendicular to one another are called the right faces.

Def. The face of a right angled trehedral which joins each of the two right faces is called the oblique face.

Def. If a right trehedral be cut by a plane perpendicular to one of the edges of the oblique face, this edge is called the adjacent edge, the remaining edge of the oblique face is called the opposite edge, and the edge between the two right faces is called the right edge.

Def. If the two right faces of a right angled trehedral be both acute, the trehedral is called a right trehedral.

Def. The right face which terminates in the adjacent edge is called the adjacent face, and the right face which terminates in the opposite edge is called the opposite face.†

---

* Generally speaking, timber is divided into solids, of which each is contained by six rectilinear plane faces. The solids thus formed for the construction of buildings have various names according to their relative magnitudes or their destination.

The faces of such solids terminate in twelve edges called by workmen *arrises*, which are right lines, because the intersection of every two planes is a right line. The twelve edges again terminate in eight points, and three of the edges meet each other in each of the eight points. Any three of the right lines which thus meet contain between every two of them a face of the solid. But as the faces are at right angles to one another, the edges are also at right angles to one another. None of the eight trehedrals having the three planes perpendicular to one another, can ever be an object of research, all the parts being known.

But as timber may be cut by planes (that is by saws) in all positions, we may have trehedrals of various forms in which the angles containing the faces may be of all magnitudes.

As we shall frequently make use of the words oblique angle, it will be proper to explain its meaning. An oblique angle is an angle in which one of the sides containing it is not perpendicular to the other, and may therefore be either an acute angle or an obtuse angle. An oblique plane has always a reference to another plane, and implies that the two planes are not perpendicular to each other.

The cutting of timber contained under plane surfaces depends entirely upon a knowledge of the trehedral, and there is no object constructed in parts with plane joints which does not embrace some case or other of trehedral solutions. We shall therefore proceed to give the remaining definitions, and then to the solution of the different cases.

† PROPOSITION.—*Theorem* 1.

If each of the three faces of a trehedral be acute, its section made by a plane perpendicular to one of the edges, if sufficiently extended, will be a triangle of which a side will be contained in each of the three faces.

For let C V, B V, and A V (plate i. fig. 1) be the three edges of the trehedral, and let the angles of the three faces C V B, C V A, and B V A be each an acute angle, and let the plane F G be drawn perpendicular to one of the edges V C, and let the planes of two of the faces which meet in this edge be prolonged to meet the plane F G, thus let the face C V B meet the plane F G in the line C E and let the face C V A meet F G in the line C D.

Then because the intersection of two planes is a right line, the lines C E and C D are right lines, and because a right line perpendicular to a plane is also perpendicular to every right line drawn in the plane from the point in which the line intersects the plane, the right line C V is perpendicular to the two right lines C E, C D. Moreover, because the angles C V B and V C E are both in the same plane, and because the angle C V B is an acute angle and the angle V C E is a right angle, the two right lines V B and C E will meet; but C E is in the plane F G, therefore V B will meet the plane F G. In the same manner it may be shown that V A will meet the plane F G. Let the edge V B meet the plane F G in E, and the other V A meet it in D, therefore since the intersection of every two planes is a right line, D C E is a rectilinear triangle.

* The definitions hitherto given are general for all kinds of trehedrals; but as two adjacent planes of timbers are generally perpendicular to one another, the oblique trehedral seldom occurs in practice, and whenever it does so the object of inquiry may be obtained by dividing such a trehedral into two others, of which each may have two planes perpendicular to one another. It is therefore to this more limited species of trehedrals to which we shall direct the attention of the reader.

† PROPOSITION.—*Theorem* 2.

In a right trehedral, the three triangles formed by the edges of the trehedral and the sectorial triangle, as also the sectorial triang itself, will be all right angled triangles.

For in fig. 2 let the trehedral be V A C B, in which the point V is

Def. In the sectorial triangle A B C, the angle A is called the vertical angle, the leg adjacent to the vertical angle is called the adjacent leg, and the leg opposite to the vertical angle is called the opposite leg.

Def. The common leg of the sectorial triangle, and the triangle upon any face of the trehedral formed by two edges and that leg, is called the sectorial leg of the triangle in that face.*

Def. The angle contained by the oblique face and one of the right faces is called the inclination of these faces.

Def. The point in which any two of the sides of the sectorial triangle meet each other in one of the edges of the trehedral is called the sectorial point.†

Def. In a right trehedral the two inclinations and the three faces are called parts.

The right angle being always given is not one of the parts. Hence in every right trehedral the number of parts are five. In every right trehedral, when two of its parts are given, a third may be found at one operation.

(1.) In all the diagrams the oblique face is denoted by A V B, the adjacent face by A V C and the opposite face by B V C.

The sectorial triangle is denoted by A B C, and the three sectorial points by A, B, C.

As one inclination is only concerned in our operations, this inclination is denoted by B′ A C or by B A′ C: *viz.*, by B′ A C when the sectorial triangle is placed upon the sectorial line A C of the adjacent face, or by B A′ C when the sectorial triangle is placed upon the sectorial line B C of the opposite face. It being convenient to place the sectorial triangle sometimes upon the one, and sometimes upon the other of these lines.

All the triangles may be entirely detached in the construction, but it is convenient to adjoin in the same manner as they are in the solid. This not only saves lines, but renders the diagram more evident in order to bring the corresponding edges in contact, and thereby form the trehedral.

Keeping the above notation in view, the sectorial lines A B and A C will be each perpendicular to A V, and C B perpendicular to C V.*

---

the vertex, and A C B the sectorial triangle, and VA be the edge to which the plane of the sectorial triangle A B C is perpendicular, and let the two right faces be A V C and B V C, and the oblique face be A V B.

The right line V A being perpendicular to the plane of the sectorial triangle A B C will be perpendicular to every right line drawn in the plane from the point A, in which the perpendicular meets the plane; hence V A is perpendicular to each of the right lines A C and A B; therefore, the two triangles V A B and V A C are each right angled at the point A, and are consequently right angled triangles.

Moreover, because the right line A V is perpendicular to the plane B A C, every plane passing along A V is perpendicular to the plane B A C, therefore the plane V C A is perpendicular to the plane A C B; and reciprocally the plane A C B is perpendicular to the plane V C A. But because V C A and V C B are the right faces, the plane V C B is perpendicular to the plane V C A; hence each of the planes A C B and V C B is perpendicular to the plane A C V; therefore their common section B C is perpendicular to the plane A C V: again, a right line which is perpendicular to a plane is perpendicular to every right line drawn in that plane from the point in which the perpendicular meets the plane; hence B C is perpendicular to each of the right lines C V, C A; therefore the triangle V C B is right angled at C, and the triangle A C B is also right angled at C; hence all the four triangles A V B, A V C, B V C, and A B C, are right angled triangles.

Cor. 1. Because the triangle V A B is a right angled triangle, and the right angle is at the sectorial point A, the angles A V B and A B V are each an acute angle; therefore the angle A V B of the oblique face is always less than a right angle, when the angles of the right faces are each less than a right angle.

Cor. 2. Because the sectorial triangle A B C is a right angled triangle of which the vertex of the right angles is in the right edge at C, each of the two angles contained by the oblique plane and each of the right faces is an acute angle.

SCHOLIUM.

From these two corollaries it appears that the sum of the angles of the three faces is less than three right angles, and the sum of the angles contained by every two faces is also less than three right angles.

* *Cor.* The vertical angle A of the sectorial triangle is the dihedral angle formed by the planes of the oblique and adjacent faces, and the hypotenuse A B, the adjacent leg A C, and the opposite leg B C of this triangle are respectively the sides of the lateral triangles opposite the angle of the oblique face, the angle of the adjacent face, and the angle of the opposite face.

Hence if these triangles be all developed upon one plane, the lines which are common in the solid are equal in the developement; that is, the vertical angle A of the sectorial triangle is equal to the angle contained by a right face and the oblique face; the hypotenuse of the sectorial triangle is equal to the sectorial leg in the oblique face; the adjacent leg of the sectorial triangle is equal to the sectorial leg in the adjacent face; and the opposite leg of the sectorial triangle is equal to the sectorial leg in the opposite face.

† PROPOSITION.—*Theorem* 3.

Every right angled trehedral having one or both its right faces obtuse, may be reduced to a right trehedral, or to one which shall have both its right faces acute.

For let in fig. 3 one of the right faces of each of the four adjoining trehedrals, A V B C, A V C D, A V D E, and A V E B, be upon the same base B C D E, so that the oblique faces may coincide two and two in the plane B A D, and the right faces may also coincide two and two in the plane C A E, and let the right faces in the plane B C D E be called the bases, and the other right faces the vertical faces.

The bases of these trehedrals being right lines cutting one another, are either adjacent or opposite, that is, in opposite angles.

Now let each of the three trehedrals A V C D, A V D E, and A V E B, be compared with the trehedral A V B C, in which both the right faces A V C and B V C are acute. Then, because the angle B V C is acute, and the two angles B V C and C V D are together equal to two right angles, the angle C V D is obtuse; and because C V D and D V E are equal to two right angles, and the angle C V D is obtuse, the angle D V E is acute; and because D V E and E V B are equal to two right angles, and the angle D V E is acute, the angle E V B is obtuse.

Moreover, because the angles A V C and A V E are together equal to two right angles, and the angle A V C is acute, therefore the angle A V E is obtuse; hence the trehedral V A C D has an obtuse base, C V D, and an acute vertical face C V A, and is joined to the trehedral V A B C by the common vertical face A V C; the trehedral V A D E has an acute base D V E and an obtuse vertical face A V E, and the two trehedrals A V D E and A V B C are opposite each other, and have their vertical faces in one plane, and their oblique faces in another plane; and lastly, the trehedral V A B E has an obtuse base B V E and an obtuse vertical face A V E, and the two trehedrals V A B E and V A B C are joined to each other by the common oblique face A V B, and hence the proposition proposed to be proved is true.

COROLLARIES.

Hence, 1. If a right angled trehedral, of which the base is obtuse, and the vertical face be given, find the adjacent trehedral, so that the vertical face may be common to the trehedrals.

2. If a right angled trehedral, of which the base is acute, and the vertical face obtuse, be given, find the trehedral upon the opposite base.

3. If a right angled trehedral, of which both its base and vertical face are given, find the adjacent trehedral so that the two trehedrals may have a common oblique face.

In any of the three cases the trehedral to be found will have all its parts, and the like parts of both will be either equal or supplementary to each other. The common faces and opposite bases will always be equal, as well as the dihedral angles which terminate in the same right line, and upon the same side of this right line, and the adjacent faces will be supplements of each other, as well as the dihedral angles adjacent.

* Notwithstanding the variety of cases, which are sixteen in number, every construction is extremely easy, as there is no case

PROPOSITION.—*Problem* 1.

(2.) Any two of the three parts, the inclination, the adjacent face, and the oblique face of a right trehedral, being given to find the third part.

Preliminary.

The adjacent and oblique faces A V C, A V B being constructed, the triangles upon these faces will have a common leg V A upon the adjacent edge, therefore the sectorial line upon each face will be perpendicular to V A; hence the construction may be found from one of the three following rules.

RULE I.

(3.) When the inclination is required, the adjacent and oblique faces must necessarily be given.

1. From any convenient point, A, in the adjacent edge V A, draw the sectorial line upon each of the two given faces.

2. The sectorial line upon the adjacent face, and the sectorial line upon the oblique face being drawn, the adjacent leg and hypotenuse of the sectorial triangle will be given to find the vertical angle.

3. The vertical angle being found will be the inclination required.*

RULE II.

(4.) When the oblique face is required, the adjacent face and the inclination must necessarily be given.

1. Upon the adjacent face draw the sectorial line.

2. Having drawn the sectorial line upon the given adjacent face, the adjacent leg and the vertical angle of the sectorial triangle are given to find the hypotenuse.

3. Having found the hypotenuse of the sectorial triangle, the lateral and sectorial legs of the triangle upon the oblique face will be given to find the angle at the vertex, or opposite the sectorial side.

4. The angle at the vertex being found, will be the angle of the oblique face required.†

RULE III.

(5.) When the adjacent face is required, the oblique face and the inclination must necessarily be given.

1. Upon the given oblique face draw the sectorial line.

2. Having drawn the sectorial line upon the given oblique face, the hypotenuse and an angle of the sectorial triangle are now given to find the adjacent leg.

3. Having found the adjacent leg of the sectorial triangle, the lateral leg and sectorial leg of the triangle upon the adjacent face are now given to find the vertical angle.

4. The vertical angle of the lateral triangle being found is the angle of the adjacent face required.*

PROPOSITION.—*Problem* 2.

(9.) Any two of the three parts, the inclination, the oblique and opposite faces of a right trehedral being given, to find the remaining third part.

The oblique and opposite faces A V B, B V C, fig. 6, 7, and 8, being concerned, the lateral side of the two adjoining triangles will be their common hypotenuse B V; and the sectorial lines will therefore be perpendicular one to each of the unconnected edges A V and C V. Hence, by the following Rules, the part required may be found.

RULE I.

(10.) When the inclination is required, the oblique and opposite faces will necessarily be given.

1. Draw the sectorial leg upon each of the two given faces.

2. The sectorial leg upon the oblique face, and the sectorial leg upon the opposite face being drawn, the hypotenuse and the opposite leg of the sectorial triangle will be given to find the vertical angle.

---

that requires more than three right angled triangles in the diagram, and when the same triangle occurs, it is uniformly denoted by the same letters. Though the number be sixteen, seven or eight of these are sufficient for our present purpose.

* *Example* 1. *to* RULE I. PROPOSITION.

(6.) Given the oblique face A V B, fig. 4 or 5, and the adjacent face A V C of a right trehedral, to find the inclination.

1. Take any convenient point A in the adjacent edge V A, and draw the right lines A B. A C, each perpendicular to A V.

2. Draw C B′ perpendicular to A C, and from the point A with the distance A B cut the perpendicular C B′ in B′. Join A B, and the angle C A B′ is the inclination required.

† *Example* 2.

(7.) Given the adjacent face A V C, and the inclination of a right trehedral, to find the oblique face A V B.

1. Having as before assumed the point A in V A, draw the right line A C perpendicular to A V.

2. At the point A with the right line A C make the angle C A B′ equal to the given inclination, and draw the right line C B′ perpendicular to A C.

3. Draw the right line A B perpendicular to A V; make A B equal to A B′, join B V, and A V B is the angle of the oblique face required.

* *Example* 3.

(8.) Given the oblique face A V B, the inclination B A C of a right trehedral, to find the adjacent face A V C.

1. Draw the right line A B perpendicular to A V.

2. Draw A C perpendicular to A V; make the angle C A B′ equal to the given inclination, make A B′ equal to A B, and draw B′C perpendicular to A C.

3. Join V C, and A V C will be the angle of the adjacent face required.

In order to find any of the three parts required by computation, we shall here give the investigation of the three formulæ, and as this can be done according to any of the three Rules, we shall adapt this process to Rule I., in which the dihedral angle is required to be found as being the most simple.

Let VA = radius = 1; then will A B = tan AVB, and A C = tan AV C.

Now in the right angled triangle A B′ C are given the adjacent leg A C and the hypotenuse A B to find the vertical angle C A B′. By trigonometry making radius upon A B′ and the cosine therefore upon A C, the following analogy will give an equation from which any of the three parts may be found.

$$AB' : AC :: \text{radius} : \cos CAB' = \frac{AC \times \text{rad}}{AB'} = \frac{\tan AVC}{\tan ABV},$$

hence

$$\tan AVC = \tan AVB \times \cos CAB',$$

$$\tan AVB = \frac{\tan AVC}{\cos CAB} = \tan AVC \times \sec CAB$$

because $\sec = \frac{1}{\cos}$,

$$\cos CAB = \frac{\tan AVC}{\tan AVB} = \tan AVC \times \cot AVB;$$

because $\cot = \frac{1}{\tan}$.

These equations in terms of the trehedral will be thus expressed:
tan adjacent face = tan opposite face × cos inclination.
tan oblique face = tan adjacent face × cos inclination.
cos inclination = tan adjacent face × cot oblique face

3. The vertical angle being found, will be equal to the inclination.*

Rule II.

(11.) When the opposite face is required, the oblique face and the inclination must necessarily be given.

1. Draw the sectorial leg upon the given oblique face.

2. The sectorial leg upon the oblique face being found, the hypotenuse and the vertical angle of the sectorial triangle will now be given to find the opposite leg.

3. The opposite leg of the sectorial triangle being found, the hypotenuse and the sectorial leg of the triangle upon the opposite face will be given, to find the angle of this opposite face.

4. The angle of the opposite face being found is the angle required.†

Rule III.

(12.) When the oblique face is required, the opposite face and inclination must necessarily be given.

1. Draw the sectorial line upon the given opposite face.

2. The sectorial line upon the opposite being found, the vertical angle and opposite leg of the sectorial triangle will be given, to find the hypotenuse.

3. The hypotenuse of the sectorial triangle being found, the hypotenuse and sectorial leg of the triangle upon the oblique face will be given, to find the angle opposite to the sectorial leg.

4. The angle opposite the sectorial leg being found, will be the angle of the oblique face required.‡

Proposition.—*Problem* 3.

(16.) Any two of the three parts, the inclination, the two right faces of a right trehedral being given, to find the third, or remaining part.

Preliminary.

The two right faces being concerned, the lateral edge of the two adjacent triangles will be the right edge, and will be the leg of the triangle upon the opposite face, and the hypotenuse of the triangle upon the adjacent face. Hence, the part required may be found by one of the three following Rules.

Rule I.

(17.) When the inclination is required, the two right faces must necessarily be given.

1. Draw the sectorial line upon the adjacent face, and the sectorial line upon the opposite face.

2. Having drawn the sectorial lines upon the adjacent and opposite faces, the adjacent and opposite legs of the sectorial triangle will be given to find the vertical angle.

3. The vertical angle being found will be the inclination required.*

Rule II.

(18.) When the opposite face is required, the inclination and adjacent face must necessarily be given.

1. Draw the sectorial line upon the adjacent face.

2. The sectorial leg being drawn upon the adjacent face, the vertical angle and adjacent leg of the sectorial triangle will be given to find the hypotenuse.

3. The hypotenuse of the sectorial triangle being found, the lateral and sectorial legs of the triangle upon the opposite face will be given, to find the angle opposite to the sectorial leg.

4. The angle opposite to the sectorial leg being found, will be the angle of the opposite face required.†

---

* *Example to* Rule I. Proposition II.

(13.) Given the oblique face B V A, (fig. 6 or 7,) and the opposite face B V C of a right trehedral to find the inclination.

1. Draw the right line B C perpendicular to C V, and the right line B A perpendicular to A V.

2. From the point B, with the distance B A, cut V C, or V C prolonged in A′, and join A′ B. Then B A′ C is equal to the inclination required.

This case is applicable to the ranging of hip rafters, and to finding the dihedral angles of the regular solids.

† *Example to* Rule II.

(14.) Given the inclination B A C, (fig. 8,) and the oblique face A V B of a right trehedral, to find the opposite face B C V.

1. Draw B A perpendicular to A V.

2. At the point A, with the right line A B, make the anglo B A C′ equal to the given inclination, and draw B C′ perpendicular to A C′.

3. Upon V B as a diameter describe the semicircle B C V; from the point B, with the distance BC′, cut the semicircular arc in C, and join C V. Then B V C is the angle of the opposite face required.

‡ *Example to* Rule III.

(15.) Given the inclination B A′ C, (fig. 8.) and the opposite face B V C of a right trehedral, to find the oblique face.

1. Draw B C perpendicular to V C.

2. In V C, or in V C prolonged, take any point, *e*, and draw *e d*, making the angle C *e d* equal to the given inclination; and from B draw the right line B A′ parallel to *d e*, meeting C V in A′.

3. Upon V B as a diamoter describe the semicircle B A V; and from the point B, with the distance B A′, cut the semicircle in A. Join A V and A B. Then the angle B V A is equal to the angle of the oblique face required.

The methods of finding the formula when two parts out of the three parts concerned in the proposition are given to find the third, are similar to those investigated in the note to the example of Rule I. It will, therefore, be only necessary to give the three expressions in terms of the right trehedral.

1. sin opposite face = sin oblique face × sin inclination.
2. sin oblique face = sin opposite face × cosec inclination.
3. sin inclination = sin opposite face × cosec oblique face.

* *Example to* Rule I. Proposition.

(20.) Given the adjacent face A V C, (fig. 9.) and the opposite face B V C of a right trehedral, to find the inclination.

1. Draw C A perpendicular to A V, and C B perpendicular to C V.

2. Draw C B′ perpendicular to C A, and make C B′ equal to C B. Join A B′; then the vertical angle C A B′ is equal to the inclination required.*

Or thus, instead of 2. (fig. 10 and 11.)

2. Having drawn C A and C B as in 1. From the point C, with the distance C A, cut C V, or C V prolonged in A′, and join A′ B. Then the vertical angle C A′ B is the inclination required.

N.B.—This Problem is applied in Carpentry to the ranging of hip rafters; and in Sciography to the shadows of cylinders in all positions, as also to the shadows of polygonal and circular rings.

† *Example to* Rule II.

(21.) Given the inclination B′ A C, (fig. 9,) and the adjacent face A V C of a right trehedral, to find the opposite face B V C.

1. In the connecting line V C of the two faces concerned, take any point C, and draw C A perpendicular to A V.

2. At the point A, with the right line A C, make the angle C A B′ equal to the given inclination, and draw C B′ perpendicular to C A.

3. Draw C B perpendicular to C V; make C B equal to C B′, and join B V. Then C V B is the angle of the opposite face required.

Or thus, instead of 2. and 3.

2. In C V, (fig. 10 and 11,) or in C V prolonged, cut off the part C A′ equal to C A, and make the angle C A′ B equal to the given inclination. Draw B C perpendicular to C V.

3. Join B V, and C V B is the angle of the opposite face required.

N.B. This Problem is applied in perspective in finding the vanishing line of a plane, and in Dialling to finding the hour lines, the angle which the style makes with the substyle being given.

* Formula for the arithmetical computation.

tan opposite face = tan inclination × sin adjacent face.
tan inclination = tan opposite face × cosec adjacent face.
tan adjacent face = tan opposite face × cot inclination.

RULE III

(19.) When the adjacent face is required, the inclination and opposite face must necessarily be given.

1. Having drawn the sectorial line upon the given opposite face, the vertical angle and opposite leg of the sectorial triangle will be given, to find the adjacent leg.

2. The adjacent leg of the sectorial triangle being found, the hypotenuse and sectorial leg of the triangle in the adjacent face will be given, to find the angle opposite to the sectorial leg.

3. The angle opposite to the sectorial leg being found, will be the angle of the adjacent face required.*

PROPOSITION.—*Problem* 4.

(23.) Any two or three faces of a right trehedral being given to find the third.

General Rule.

When any one of three faces is required, the other two must necessarily be given, and these may either be the two right faces or one right face and the oblique face. If the two right faces be given, the lateral right edge V C must be the connecting edge, but if the oblique face and a right face be given, the right face may always be supposed to be the adjacent face A V C, and consequently A V the adjacent edge.

As the face to be found may be attached to either of the unconnected edges of the two given faces, the lateral side of the triangle to be found, attached to the unconnected edge, must either be a leg or hypotenuse of the triangle in the face required, but as one of the two may always be chosen, the leg will afford the most easy construction; hence,

If the lateral edge, to which the third face of the trehedral is connected, be a leg, draw a right line from the sectorial point perpendicular to the leg, and the sectorial leg will be upon this perpendicular from the sectorial point, and from the vertex of the lateral faces with the length of the other unconnected lateral edge cut the perpendicular, join the point of section and the vertex. Then the angle at the vertex will be the angle of the face required.

But if the lateral edge to which the third face is connected be the hypotenuse of the triangle in the face required, describe a semicircle on this hypotenuse as a diameter, and from the vertex of the trehedral faces with the length of the other unconnected lateral edge cut the semicircular arc. Join the vertex of the faces and the point of section, and the angle by the line and the diameter of the semicircle is the angle of the face required.

Though the construction is easier when the face required is attached to a leg, yet as the intersection of the arc described from the vertex and the sectorial leg is sometimes occasionally very oblique, a preference on this account, when it so happens, may be given to the other construction, when the face required is attached to the hypotenuse.

N. B. When the two right faces are given, either may be made the adjacent face.*

---

* *Example to* RULE III.

(22.) Given the inclination B A′C (fig. 10 and 11) and the opposite face B V C of a right trehedral, to find the adjacent face A V C.

1. In V C take any convenient point C, and draw C B perpendicular to C V.

2. In C V, or in C V prolonged, take any convenient point *e*, and draw *e d*, making the angle C *e d* equal to the given inclination. Draw B A′ parallel to *d e*, making C V, or C V prolonged in A′.

3. Upon C V as a diameter describe the semicircle C A V; and from the point C with the distance C A′ cut the semicircumference in the point A. Join A C and A V, then C V A is the adjacent face required.

N. B. This Problem is used in Sciography, in order to find the lines of light and shadow in a cone.

* *Example to* PROPOSITION IV.

(24.) Given the two right faces of a right trehedral to find the oblique face.

Let the adjacent face be C V A, (fig. 12,) and therefore the opposite face C V B′

Now, in the adjacent face, the sectorial leg is perpendicular to the adjacent edge V A, and in the opposite face the sectorial line is perpendicular to the right edge; therefore,

1. Draw C A perpendicular to V A, and C B′ perpendicular to C V.

2. Let it now be required to find the oblique face attached to the adjacent edge V A. Draw A B perpendicular to A V, and from the point V with the distance V B′ cut the right line A B in B, and join V B. Then A V B is the oblique face required.

SCHOLIUM.

The four Propositions now given will be found to apply to every useful purpose in Carpentry, Perspective, Sciography, and Dialing. As to the case in which the two dihedral angles and one of the right faces, and that in which the two dihedral angles and the oblique face are concerned, we shall leave for the exercise of the reader, who will now, if he understands the preceding Propositions, not be at any loss to supply the two Theorems just now mentioned.

The three faces being the parts of the trehedral concerned, any two being given as above, we shall here give the investigation of the formula for finding any one of the three parts from the other two being given.

Let $CV = \text{radius} = 1$, then will $VB = \sec CVB$, and $VA = \cos CVA$. Now since by construction $VB = VB$, $VB' = \sec CVB$; hence in the triangle $B'AV$ the hypotenuse $VB = \sec CVB$, and the leg $VA = \cos CVA$, are given to find the angle BVA; therefore, making radius upon BV, the cosine of the angle BVA will be upon VA; hence

$$VB' : VA :: \text{rad} : \cos BVA = \frac{VA \times \text{rad}}{VB'} = \frac{\cos CVA}{\sec CVB} = \cos CVA \times \cos CVB.$$

Hence $\cos CVA = \cos BVA \times \sec CVB$;

and $\cos BVA = \cos CVA \times \cos CVB$; these expressed by the parts of the right trehedral, will be

cos one right face = cos oblique face × sec other right face.

cos oblique face = cos one right face × cos other right face.

But before we dismiss this part of our Treatise, it will be found useful to show how this last Problem may be constructed by another principle independent of the trehedral.

(25.) Let *g* V *d* (fig. 13) be one of the right faces, and let *g* V be the edge of the other right face which is common to the two faces, and let V be the common vertex of these faces.

Through any point *g* in V *g* draw *g b* in any convenient position, and prolong *d* V to any convenient point A. From the point *g* with the distance *g* A describe the arc A *b*, and from the same point A with the distance *g* V describe the arc V *c* meeting *g b* in *c*. Make the angle *g c* F equal to the angle contained by the other given right face, and draw *g* F perpendicular to *g b*.

From the point F with the radii F *b*, F *c* describe the arcs *b* D, and *c* E, and from any convenient point E in the arc *c* E with the distance V A cut the arc *b* D in D. Join F E, E D, and F E D will be the supplement of the angle required.

For suppose the other right face to be placed upon *g* V with its vertex in V, and to be perpendicular to the plane *g* V *b*. Draw *g* F′ in the vertical face perpendicular to *g b*; then the vertical face will meet the oblique face in a right line F′ V which is the hypotenuse of a right angled triangle of which *g* V is the base, and therefore the angle F′ *v d* will be the angle of the oblique face. Imagine *g* A and F′ A to be joined, then F′ A will be the subtense of the angle F′ V A, which will be the supplement of the oblique face. Now because *g c* is equal to *g* V, and *g* F is equal to the perpendicular *g* F of the imaginary vertical face, the right angled triangle *c g* F will be equal to the right angled triangle V *g* F′ in the vertical face; hence the hypotenuse *c* F is equal to the hypotenuse *c* F′ in the vertical face. In like manner,

Definitions.

Def. A plane to which the relations and positions of points, lines, and planes are given, and on which, from these data, other relations are determined, is called the *primitive plane.*

Def. A point, line, or plane is said to be in space when it is situated out of the primitive plane, and a line or plane is still said to be in space, even though one extremity of the line or plane should come in contact with the primitive plane.

Def. If a right line be drawn from any point in space perpendicular to the primitive plane, the point in which the right line meets the primitive plane is called the *projection of the point,* and the right line itself is termed the *projectant of that point.*

Def. A right line drawn through the projections of two points of another right line in space, is called the *projection of this right line.*

Def. A line or a point is said to be given when its relations to the primitive plane are given.

Def. A right line is given in space when the projection and inclination of the line is given, or when the projections and projectants of two of its points are given, or provided the line meet the primitive plane when the point of coincidence and the projection and projectant of one of its points are given.

Def. A point is said to be given either when it coincides with the primitive plane, or when its projection and projectant are given, or when the distances from the point to three given points upon the primitive plane are given.

Def. A right line is said to be given either when it coincides with the primitive plane, or when its projection and inclination are given, or when it is parallel to the primitive plane, and the projection of the line and the projectant of one of its points are given; or any line obliquely situated is said to be given when the projections and projectants of two of its points are given; or a right line meeting the primitive plane is also said to be given, when the point of contact and the projection and projectant of one of its points are given.

Def. A parallel plane is understood to be that which is parallel to the primitive plane.

Def. An oblique plane is that which has an inclination to the primitive plane.

As the intersection of two planes is a right line, the oblique plane will meet the primitive plane in a right line.

Def. The right line in which an oblique plane meets the primitive plane, is called the *trace of the oblique plane.*

Def. The trace of a plane is said to be given when a right line is drawn upon the primitive plane, so that the edge of the oblique plane, supposed to be a right line, may coincide with the line thus drawn for its trace.

Def. A parallel plane is said to be given when the projectant of any one of its points are given.

Def. An oblique plane is said to be given when its trace and inclination to the primitive plane are given.

Or when its trace and the projection and projectant of one of its points are given.

Or when the projection and projectants of three of its points are given.*

Proposition.—*Problem* 1

(26.) To find the primitive inclination of a plane which shall have a given trace, and which shall contain a given right line meeting the trace.

Here in the right trehedral are given the vertical and primitive faces to find the primitive inclination.

Now as the primitive inclination is the inclination concerned, the primitive face is the adjacent face A V C, and the vertical face the opposite face B V C.

This Proposition, therefore, becomes the following Problem:

The adjacent face A V C and the opposite face B V C of a right trehedral being given to find the inclination..

The solution of this Problem will be found as in (20.) fig. 9.†

Proposition.—*Problem* 2.

(27.) To find the vertical inclination of a plane which shall have a given trace, and shall contain a given right line meeting the trace.

Here in the right trehedral are given the vertical and primitive faces, to find the vertical inclination.

Now as the inclination concerned is the vertical inclination, the vertical face must be the adjacent face A V C, and the primitive face the opposite face B V C.

This Proposition, therefore, becomes the following Problem:

The adjacent face A V C and the opposite face B V C, of a right trehedral being given to find the inclination.‡

---

if F *b* supposed to be joined, the hypotenuse F *b* will be equal to the hypotenuse F A in the oblique face. But F E is equal to F *c*, and F D equal to F *b*; therefore the three sides of the triangle in the oblique face are equal to the three sides of the triangle F E D; therefore the obtuse angle F E D will be equal to the supplement of the oblique face.

* The angle contained by the trace of a plane, and the projection of a right line contained in the plane, is one of the right faces of a right trehedral, and is situated in the primitive plane; because both the trace of the plane and the projection of the right line are situated in the primitive plane. The angle of projection of the right line is the other right face of the trehedral, and is in consequence in the vertical plane; and the angle which the right line makes with the trace of the plane is the oblique face of the trehedral.

When it is said that an oblique right line is given, it must be understood that the projection and angle of the projection of the right line is given.

When it is said that an oblique right line is required, it must be understood that the projection and angle of projection are required.

When the trace of a plane is required, it must be understood that the projection of the right line must be given, and the angle contained by its projection and the trace of the plane must either be given or found.

When the projection of a right line contained in a plane is required, it must be understood that the trace of the plane must be given, and the angle which the trace makes with the projection of the line found.

Of the two inclinations of a right trehedral, the one, formed by the oblique face and the primitive plane, is called for the sake of brevity the *primitive inclination;* and the other, formed by the oblique and vertical faces, is called the *vertical inclination.*

When only one of the two inclinations is concerned in the proposition, this inclination must be either given or required, but whichever of the two it is, the right face which forms the inclination with the oblique face must be the adjacent face; that is, when the primitive inclination is given or required, the *primitive face* must be the *adjacent face;* and when the vertical inclination is given or required, the vertical face must be the adjacent face.

† This Problem is applied to the shadows of cylinders in all positions, to a given position of the Sun's rays, as also to the shadows of polygonal and circular rings.

‡ This Problem only differs from the last in the vertical inclination being required in this, and the primitive in the last; but both are resolvable into the very same case of the trehedral, (20.) fig. 9, when we abstract the trehedral from any position in regard of the primitive plane.

This is the case which applies to the ranging of hip rafters, when the angle which the hip makes with its projection, and the angle which the projection makes with the wall plate, are given.

Proposition.—*Problem* 3.

(28.) To find the inclination of a plane, so that the plane shall have a given trace, and shall be parallel to a given right line.

Let D E (fig. 14) be the trace of the plane, C′ V′ the projection of the right line, V any convenient point in D E, and C any convenient point in V′ C′.

Make the angle C′ V′ B′ equal to the angle of projection, and draw V C parallel, and make it equal to V′ C′. Draw C A perpendicularly upon D E, C B perpendicular to C A, and C′ B′ perpendicular to C′ V′. Make C B equal to C′ B′, and join A B. Then C A B is equal to the inclination required.

This Problem is equivalent to that of having the two right faces of a right trehedral to find one of the inclinations, which is here the horizontal inclination, the two right faces being C V A and C′ V′ B′. (17.) (20.)

Proposition.—*Problem* 4.

(29.) The trace A V (fig. 12) of a plane, and a right line parallel to the plane being given, to draw a right line in the plane from a given point V, in the trace parallel to the given right line.

Let D E be the projection of the right line, and let V be the given point in the trace A V of the plane.

Draw V C parallel to E D, and at the point V with the right line C V, make the angle C V B′ equal to the angle of projection of the line.*

Here we have now given the two right faces C V A, C V B′ of a right trehedral, to find the oblique face, (23.) (24.) and we shall find that A V B is the oblique face required.

Thus the oblique face will be found without previously ascertaining the inclination of the planes.*

Proposition.—*Problem* 5.

(30.) Two oblique right lines being given, to find the trace of a plane which shall contain one of the lines and be parallel to the other.

Let A B (fig. 15) be the projection of one of the lines, and C D that of the other.

Draw B E parallel to C D. Draw B F′ perpendicular to B E, and B F perpendicular to B A. Make the angle B A F equal to the angle of projection of the line, of which the projection is A B, and make B F′ equal to B F. At any convenient point in B E, make the angle B *i h* equal to the angle of projection of the right line, of which the projection is C D, and draw F′ E parallel to *h i*. Join A E, then A E joined is the trace of the plane required.†

Projection.

Since a right line is given by having the position of the points in which it terminates, and a plane rectilinear figure by having the position of the right lines which form the edges, a solid bounded by plane figures is therefore given when the points terminating all the right lines which form the edges of its surfaces are given.

Now as a point is most simply determined by its projection and the length of its projectant, so also a solid in space, contained by plain faces, is most simply determined by having the projections and the heights of the projectants of all its linear extremities.

Proposition.—*Problem* 1.

(31.) Any oblique plane, and the position of a point in that plane, being given, to find the horizontal projection of the point.

Let T R (fig. 16) be the trace of the plane, and M the position of the point. Draw M *u* intersecting T R perpendicularly in *v*, and draw *v* W making the angle *u v* W equal to the horizontal inclination of the plane. From the point *v*, with the radius *v* M cut *v* W in *n*, and draw *n m* cutting *u v* perpendicularly in *m*, and *m* is the projection of the point M.

Or, thus:

(32.) Let D be the given position of the point to be projected. Draw D *d* intersecting T R perpendicularly in *g*. In T R take any convenient point *v*, and draw *v u* perpendicular to T R, and make the angle *u v* W equal to the inclination of the plane. In *v* W make *v n* equal to *g* D, and draw *n m* meeting *v u* perpendicularly in *m*. Draw *m d* parallel to T R, and *d* is the projection of D as required.*

Proposition.—*Problem* 2.

(33.) An oblique plane and the projection of a point in that plane being given, to find the position of the point in the plane.

Let T R (fig. 16) be the trace of the plane, and *d* the projection of the point. Having constructed the angle *u v* W, draw *d m* parallel to T R, meeting *v u* in *m*, and draw *m n* perpendicular to *v u* meeting *v* W in *n*. Draw *d* D perpendicular to T R, meeting T R in *g*, and make *g* D equal to *v n*, then D is the point required.

Proposition.—*Problem* 3.

(34.) To find the horizontal projection of the point in which a given right line will meet a given plane.

(35.) *Case* 1. When the given right line is parallel to the plane of projection, it will then be given when its projection is given, and when the projectant of any one of its points is given.

---

* These two last propositions will be applied to cylindrical vaulting upon an inclined plane, where they are indispensable.

† For imagine the right angled triangles A B F and E B F′, to be raised upon their bases A B and B E, until B F and B F′ be each perpendicular to the plane A B E, and the two right lines B F and B F′ will coincide, and the point F will coincide with the point F′. Let this point of coincidence be called G; the point G will be a point in the plane; but the trace A E, and consequently the points A, E are in the plane, hence the sides A G and A E are in the plane. Now, because C D and B E are parallel, and the angle B E G is, by hypothesis, equal to the angle of projection of the line of, which the projection is C D; and because the two planes which contain the lines of which C D and B E are the projections are vertical planes, they are parallel planes.

Hence the right line G E will be parallel to the right line of which C D is the projection; but if a right line be parallel to a right line in a plane, the right line is parallel to that plane; therefore the plane A E G will be parallel to the right line of which the projection is C D.

This proposition will be useful when the inclination in the Sun's rays is given, and the inclination of a right line to the primitive plane, to find the shadow of the line.

* For two right lines, one drawn from the point and the other drawn from its projection, will meet the trace of the plane in the same point, and because *g* D is equal to *v* M, the right line D M is parallel to T R; therefore the points D and M are in a right line parallel to the trace of the plane; hence the projections are also in a right line parallel to the trace of the plane; hence the point *d* is the projection of the point D.

Scholium. This last part will be often found convenient, for if many points were to be projected, it would be only necessary to contract one angle for the whole, and thus the unnecessary trouble to construct an angle equal to the inclination of the planes, for every point to be projected would be avoided.

In this case let θd (fig. 17) be the projection of the line, and let T R be the trace of the plane. In T R take any convenient point v, and draw $v u$ perpendicular to T R. Make the angle $u v W$ equal to the horizontal inclination of the plane, and from any convenient point p in $v u$ draw $p q$ perpendicular to $v u$. Make $p q$ equal to the height of the projectant of the point, and draw $q n$ parallel to $v u$, meeting $v W$ in n. Draw $n m$ perpendicular to $v u$, meeting $v u$ in m, and draw $m d$ parallel to T R. Then d is the projection of the point in which the right line will meet the plane of which the trace is T R, and of which the horizontal projection is θd.

(36.) *Case* 2. When the right line is obliquely situated to the horizontal plane, it must be given in this case either by having the projection of two of its points, and the projectants of these two points, or by having the point of coincidence, in which the line meets the plane and the projection and projectant of one of its points.

Let θd (fig. 18) be the projection of the line, θ the point of coincidence, and k the projection of one of its points, of which the projectant is known.

In T R take any convenient point v, and draw $v u$ perpendicular to T R. Make the angle $u v W$ equal to the horizontal inclination of the planes, and draw θl and $k p$ each perpendicular to $u v$, meeting $u v$ in l and p. Draw $p q$ perpendicular to $u v$, and make $p q$ equal to the height of the projectant of the point, of which the projection is k, and draw the right line $l q$. Prolong $l q$ to meet $v W$ in n, and $n m$ perpendicular to $u v$ meeting $u v$ in m. Draw $m d$ parallel to T R, and d is the projection of the point required.[*]

Proposition.—*Problem* 4.

(37.) To find the point in which a given right line will meet a given plane.

Fig. 19 exhibits the case in which the right line is parallel to the horizontal plane, and fig. 20 exhibits the case in which the right line is obliquely situated to the horizontal plane. The notation or letters of reference being the same as in fig. 17 and 18. Let θk (fig. 19) be the projection of the right line which is parallel to the horizontal plane; find the horizontal projection d of the point in which this right line will meet the given plane. (34.) Again, in fig. 20 let θ be the point of coincidence in which the right line meets the horizontal plane, and let k be the horizontal projection of a point in the line of which the projectant is known; then find (36.) the horizontal projection d of the point in which the right line in this case would meet the given plane. The remaining part of the process being the same for each figure; therefore, in fig. 19 or fig. 20, draw d D perpendicular to T R, intersecting T R in g; then the point n being already found by the construction which was necessary in finding the horizontal projection of the point in which the right line meets the given plane; it only remains to make g D equal to $v n$, and D will be the point in which the right line will meet the given plane, as required to be found.[†]

Applications of Projection in finding the Sections and Envelopes of Solids.

The surfaces of all solids are developable which can be imagined to be unfolded and extended so that every point in the surface may be in contact with a plane. Or reciprocally, the surface of a solid is developable when a plane surface can be bent upon the surface of the solid so that all its parts may be in contact with the surface of the solid.[*]

Proposition.—*Problem* 1.

(38.) To find the oblique section and covering of a given prismatic solid, the plane of the section being given.

A prismatic solid is given when the plane which contains the right section is given, and when the section itself is given in relation to the trace of the plane.[†]

Let $\alpha \beta \gamma \delta \varepsilon$ (fig. 21) be the given right section of the solid, and let $y z$ be the trace of the plane which contains the right section; also let T R be the trace of the plane which contains the section required to be found.

From the points $\alpha, \beta, \gamma, \delta, \varepsilon$ draw right lines perpendicular to $y z$, all meeting it in as many points as there are right lines, and these right lines will be the heights of the projectants of the edges. From the point of section in $y z$ draw right lines perpendicular to $y z$, and these right lines will be the projections of the edges upon the primitive plane. Let θd be the projection of the edge of which δ is the section, and let $\theta \delta$ be the perpendicular height of the point δ, and $\theta \delta$ will be equal to the projectant.

Find d, the projection of the point in which the right line, whose projection is θd, and the height of its projectant $\theta \delta$, meets the plane whose trace is T R and angle of inclination $u v W$. (34.) (35.) (36.) In the same manner find the projections $e\ a\ b\ c$ of the points in which the remaining edges would meet the plane of section.

Find the point D, in which the right line, of which the projection is $\theta \delta$, will meet the plane of section, (37.) and in the same manner find all the other points; then the right lines E A, A B, B C, C D, D E, being drawn, A B C D E will be the section required.

(39.) Let it now be required to find the developement of the successive planes and the edges of these planes which will meet the plane of section upon the right lines A B, B C, C D, D E.

---

[*] For let the plane of the angle $u v W$ be turned upon $v u$ until it become perpendicular to the horizontal plane, and upon this hypothesis, the right line $l n$, and the right line of which θd is the projection, will be in a plane, of which θl is the trace; and because θl and T R are parallel, the traces of the two planes are parallel; therefore the intersection of these planes is parallel to each of the traces; therefore since n and D are in a right line parallel to T R, the projection of the points n and D are also in a right line parallel to T R.

[†] The reason of this process is so *obvious*, from that in the preceding proposition, that no demonstration seems necessary to comprehend it. These propositions being understood, the student will find their uses in Carpentry of unlimited application, particularly in the various sections of difficult construction, as will be sufficiently exemplified in this Treatise. We shall therefore proceed to apply them in finding the sections and coverings of such solids as are developable.

[*] The covering of solids is of the greatest use in Carpentry and Joinery, in forming the soffits of arched doors, windows, or gates; the solids employed in the formation of arches are generally those of cylinders, cylindroids, or of cones, the surfaces of which are always developable.

[†] This being the case, all the edges of the solid will be perpendicular to the plane of section. But when a right line is perpendicular to a plane, the trace of the plane and the projection of the line upon another plane will be perpendicular to each other, therefore the projections of the edges of the solid in the primitive plane will be perpendicular to the trace of the plane of section. But as it is here supposed that the plane of section is perpendicular to the horizontal plane; therefore the edges of the solid and their projections will be parallel.

Prolong zy to a'', and at any convenient point α' in the prolongation $y a''$ from $\alpha' a''$ cut off $\alpha' \beta'$ equal to $\alpha \beta$; from $\beta' a''$ cut off $\beta' \gamma'$ equal to $\beta \gamma$; from $\gamma' a''$ cut off $\gamma' \delta'$ equal to $\gamma \delta$; and from $\delta' a''$ cut off $\delta' \epsilon'$ equal to $\delta \epsilon$; and, lastly, make $\epsilon' a''$ equal to ϵa.

From the points α', β', γ', δ', ϵ', a'', draw the right lines $\alpha' a'$, $\beta' b'$, $\gamma' c'$, $\delta' d'$, $\epsilon' e'$, $a'' a''$, each perpendicular to $a'' \alpha'$; and from the points a, b, c, d, e, in the projection of the section, draw the right lines $a a'$, $b b'$, $c c'$, $d d'$, $e e'$, $a a''$, parallel to $z a''$. Join $a' b'$, $b' c'$, $c' d'$, $d' e'$, $e' a''$, then will the covering required be the rectilinear figure $a'' a' a' b' c' d' e' a''$.

Fig. 1, pl. ii. exhibits another example in which the figure of the solid is a semicylinder instead of a prism.

Proposition.—*Problem* 2.

(40.) To find the envelope or covering of a right semicone, the axis being situated in the horizontal plane.

Let $a b c$, pl. ii. fig. 2, be the section of a cone along its axis, and let $b c$ be the section of the base, then the sides $a b$ and $a c$ of this section are equal to each other, and each equal to any edge whatever of the cone; and consequently, the envelope or covering will be the sector of a circle of which the radius will be equal to any edge of the cone, and the length of the arc equal to the semicircular arc of the base; therefore, upon $b c$ as a diameter describe the semicircle $b f c$, and from the summit a of the cone with the length $a c$ of one of the edges describe the arc c F B, and make the arc c F B equal to the semicircular arc $c f b$. Join B a, and $a c$ B is the envelope required.*

Proposition.—*Problem* 3.

(41.) Given upon the primitive plane a section of a right cone along the axis, the envelope of the semicone, and a point in the envelope to find the projection of that point upon its surface.

Let $a b c$ (fig. 2, plate ii.) be a section of the cone, and let A C B be the envelope of the semicone, and let D be the point in the surface which is required to be projected.

Through the points a and D draw the right line a F meeting the arc c B in F, and upon $b c$ describe the semicircle $b f c$. Transfer the arc c F of the sector to the semicircular arc, making $c f$ equal to c F, and draw $f e$ perpendicular to $b c$. Join $e a$, and from the point a as a centre, with the distance a D, describe the arc Dg meeting $a c$ in g. Draw $g d$ parallel to $c b$, meeting $e a$ in d, and d is the projection of the point D.†

Proposition.—*Problem* 4.

(42.) Given the projection of a point in the surface of a right cone upon a section passing along its axis, to find the position of the developement of the point.

Suppose the cone to be placed upon the horizontal plane, so that its section along the axis may coincide with the horizontal plane.

Let $a b c$, fig. 2, be the section along the axis, $b c$ being the section through the circular base, and consequently a diameter of this circle, and let d be the projection of the point upon the section $a b c$.

Join $a d$, which prolong to meet $b c$ in e, and upon $b c$ as a diameter describe the semicircle $b f c$. Draw $e f$ perpendicular to $b c$, and from a as a centre with the distance $a c$ describe the arc c F. Make the arc c F equal to the portion $c f$ of the semicircular arc $c f b$, and join F a. Through d draw the right line $i g$ perpendicular to A H, the axis of the cone meeting the side $a c$ in the point g, and again from the centre a, with the distance $a g$, describe the arc g D meeting a F in D; then D is the developement of the point of which d is the projection.

Proposition.—*Problem* 5.

(43.) To find the section and envelope of the portion of a right cone comprised between the horizontal plane passing along the axis and a given oblique plane.

Let $\theta l a$ (fig. 3) be the section of the cone along the axis, and let T R be the trace of the cutting plane, and let θl, θa meet T R in l and a.

Bisect the angle $l \theta a$ by the right line θd, and through any point in θd draw $y z$ perpendicular to θd, meeting θl in y and θa in z. Upon $y z$ as a diameter describe the semicircle $y i z$, and divide the semicircular arc into as many equal parts as there are intended to be points found in the section or in the curve of the envelope. Draw right lines through the points of division to meet $y z$ perpendicularly, and through the points of section in $y z$ draw the right lines θb, θc, θd, &c.; then θ is the point where the right lines θb, θc, θd, &c. meet the horizontal plane, and the perpendiculars to $y z$ are the projectants of the points in the semicircular arc. Therefore the projection and the projectant of a point in every one of the lines of which the projections are θb, θc, θd, &c., are given, as well as their common intersection at θ, to find the projection of the points in which these lines will meet the horizontal plane, (34.) (35.) (36.) and to find the points in which these lines will meet the plane of section, (37.) the trace and horizontal inclination of the cutting plane being given. Let b, c, d, &c. be the projections of the points where the right lines forming edges of the conic surface would meet the plane of section, and B, C, D, &c. the points of section of these right lines and the cutting plane; then by the last Problem (42.) find b', c', d', &c., the developement of these points of which the projections are b, c, d, &c., and the curve a B C D, &c. will be the section; moreover, the curve will be the curve of the section of the developement.

---

* For imagine the semicone to be so placed, that the sides of the section through the axis may be upon $a b$ and $a c$, and the diameter upon $b c$, and imagine the semicircle $b f c$ to be turned upon $b c$ as an axis until its plane coincide with the semibase of the cone; then as the centre of the semicircle $b f c$ coincides with the base of the cone, the two semicircumferences will coincide and become one semicircumference. Imagine, then, that the sector $a c$ B is to bent that every point in the surface of the cone will coincide with the surface of the sector; then because every right line drawn from the point a to the arc C F B is equal to every right line on the cone's surface drawn from the summit a to the semicircumference of the base, the arc of the sector will coincide with the semicircumference of the base of the cone, and therefore the cone will be entirely covered.

† For suppose the semicone to be enveloped with its envelope, then upon this hypothesis the right line $e f$ will be perpendicular to the plane $a b c$; therefore every plane passing through $e f$ will be perpendicular to the plane $a b c$; hence the plane passing along the right lines $a e$ and $e f$ will be perpendicular to the plane $a b c$; therefore the right lines $f a$ and $e a$ are in the same plane.

Again, since the section of a cone parallel to its base is a circle perpendicular to the axis of the cone, the section of the semicone will be a semicircle perpendicular to the axis; hence $g d$ a part of the diameter, and the arc of the semicircular section are both in the same plane, and since the semicircular section is perpendicular to the axis, all right lines drawn from a to the semicircular arc are equal. Now, since by hypothesis the point F coincides with f, and the right line a F with $a f$; therefore the point D will be in the right line $a f$, and because a D is equal to $a g$, the point D will be in the semicircle of which the diameter is $g i$; hence the points d, D will be both in a right line perpendicular to the plane $a b c$; therefore d is the projection of the point D.

PROPOSITION.—*Problem* 6.

(44.) To find the envelope of an oblique pyramid, given the base, the projection, and projectant of the vertex upon the horizontal plane.

Let $abcd$ (fig. 4) be the base and e the projection of the vertex. Then the figure $fa'b'c'd'a''$, which is the envelope, may be found by (25.) fig. 13. But as this is of considerable importance in the Art of Carpentry, we shall give the description here; the point e in this being the point g in that of fig. 13, and being common to all the sides ab, bc, cd, da of the base, will render the description easy.

Draw any right line ek through the point e.

From the point e as a centre with the radii ea, eb, ec, ed, &c., describe the arcs ah, bi, ck, dl, meeting ek in h, i, k, l.

Draw ef perpendicular to ek, and make ef equal to the height of the projectant of the vertex upon e. Then from the point f as a centre, with the distances of the point f from each of the points h, i, k, l, describe the arcs ha', ha'', ib', kc', ld', and in the arc ha' take the point a'' at pleasure; then from the centre a' with the side ab of the base cut the arc ib' in b', from the centre b', with the side bc of the base cut the arc kc' in c', from the centre c' with the next side cd of the base cut the arc ld' in d', and from d' with the remaining side da of the base cut ha'' in a''. Join $a'b'$, $b'c'$, $c'd'$, $d'a''$, also join fa', fa'', and $fa'b'c'd'a''$ will be the envelope required.*

PROPOSITION.—*Problem* 7.

(45.) Given the radius of a cylindric surface, to find the envelope of one of the portions of this surface comprised between two planes intersecting each other, so that the common section and one of the planes may each be perpendicular to the axis.

Let S T (fig. 5) be the axis of the cylinder.

Method First.

From any point D in S T draw D C perpendicular to S T, and make D C equal to the radius of the cylinder. Through C draw R U parallel to S T, and draw D E, making the angle C D E equal to the inclination of the planes. Let D E meet R U in E. From the point D, with the radius D C, describe the quadrantal arc A B C, and prolong D C to A′. Make the right line C A′ equal to the length of the arc A B C, and divide the arc A B C, and the right line C A′, each in the same proportion, or equally into an equal number of parts. At the points 1, 2, 3, &c. of section in the arc draw right lines perpendicular to D C; and from the points of section in D C draw right lines again perpendicular to D C to meet D E. Likewise, from the points of section in A′ C draw right lines perpendicular to A′ C, and make the perpendiculars from the points of section respectively equal to the perpendiculars comprised between the right lines D C and D E, so that the perpendiculars receding from A′ towards C may be respectively equal to the perpendiculars receding from D towards C.

Thus, for example, from the second point of section II, in the arc A B C, draw $2p$, meeting A D perpendicularly in p, and draw pm perpendicular to C D, meeting E D in m. From the corresponding second point P, in the right line A′ C, draw P M perpendicular to A′ C, and make P M equal to pm. A sufficient number of points being thus found, and the curve A′ M′ E′ drawn through these points, the triangle A C E formed by the right lines A′ C, C E, and the curve A′ M E will be half of the envelope required.

But if the abscissas be increased beyond a quadrant, the ordinates will become less and less in reverse order; and when the abscissa is equal to the semicircumference of the circle, the figure will end in an opposite vertex or point.*

Def. Any portion of the sinic figure contained by an ordinate and abscissa, and therefore the part next to the vertex, is called the *vertical segment of the sinic figure.*

Def. Any portion of the sinic figure comprised between two ordinates is called a *truncated sinic figure.*

Def. If the abscissa of the sinic figure be a quadrant, the figure is called a *semi-sinic figure.*

(46.) Hence we have another method of describing the sinic curve.

Method Second.

Let C A′, fig. 6, be the abscissa for half the length of the curve, and C E the middle ordinate perpendicular to C A′. Prolong A′ C to G, and from the centre C, and with the radius C E, describe the quadrantal arc E G. Divide the arc G E into any number of equal parts, and divide A′ C into an equal number of equal parts. From the points 1, 2, 3, &c., in the arc G E, draw the sines of the arcs G 1, G 2, G 3, &c.; and through the points of division in the right line A′ C draw right lines perpendicular to A′ C. Make the perpendiculars upon A′ C, as they recede from A′, equal to the sines of the arcs in the arc G E as they recede from G; then the curve A′ M E, drawn through all the unconnected extremities of the perpendiculars, will be the sinic curve required.

Def. If two sinic figures have the same abscissa in common and equal ordinates, these two sinic figures are called a cylindric right gore, as the fig. F A′ E.

Def. The figure comprised between two sinic curves which have a common abscissa, but the ordinates of the one less than those of the other, whether the curve be upon the same or on contrary sides of the abscissa, is called an oblique cylindric gore. Such is F N A′ M E, (fig. 6.)

PROPOSITION.—*Problem.*

(47.) To describe an oblique cylindric gore, the diameter of the cylinder being given, and the inclination of the axis to each of the planes.

---

* *Scholium.* In this manner we may approximate to the surface of an oblique cone, or that of any oblique pyramid, whatever may be the number of its sides.

* *Scholium.* The figure thus described is called the *sinic figure.* For if any succession of arcs be taken upon the circumference A B C, from the point A as their origin, as A 1, A 2, A 3, &c., the sines of these arcs will be the right lines drawn from the points 1, 2, 3, &c. perpendicularly upon the radius A D, and will be equal to the portions of the right line D C, intercepted between the point D as their origin, and the points of section of the perpendiculars drawn from 1, 2, 3, &c., upon D C. Thus, let the portion of the quadrantal arc A B C be A 2. Draw $2p$ perpendicular to D C, meeting at p. Again, let A 1 be a smaller portion of the arc, and draw $1q$ perpendicular to D C, meeting it in q. Draw pm and qr each likewise perpendicular to D C, meeting D E in m and r. Now Dp and Dq are the sines of the arcs A 1, A 2; but, by similar triangles, Dpm and Dqr, we shall have this analogy, Dp : Dq :: pm : qr; that is, pm and qr are to one another as the sines of the arcs A 2 and A 1; therefore, as the abscissas A 1, A 2, in the plane figure C A′ M E are equal to the arcs A 1, A 2; and, as the ordinates 1 Q and P M in the plane figure C A M E are equal to qr and pm, the ordinates 1 Q and P M are proportional to the sines of the corresponding arcs A 1, A 2 of the right section of the cylinder.

Let S T (fig. 7) represent the axis. Make the angles T D E and T D F equal to the inclination of the two planes, and draw D C perpendicular to S T; in D S make D A equal to the radius of the cylinder, and describe the quadrantal arc A B C. Proceed with each of the plane curves A′M E and A N F, as in (45.), and the figure F N A′M E will be that required.

Proposition.—*Problem* 8.

(48.) To describe a cylindroidal oblique gore for one quarter of the cylindroid, the vertex of the curve being in the extremity of the axis major of a right section of the cylindroid, the two axes of the right section being given.

Let S T, fig. 8, be the projection of the axes of the cylindroid upon the horizontal plane to which the axis itself is parallel, and let T D E and T D F be made equal to the angles of inclination of the axis of the cylindroid to each of the two planes which comprise between them the portion of the surface of the solid; which, (portion of the surface,) when developed, will form the cylindric gore required.

Draw D C perpendicular to S T. Join D S, make D A equal to the semiaxis minor, and make D C equal to the semiaxis major of the ellipse of the right section of the cylindroid. Having described the elliptic quadrant A B C, proceed in the same manner as in the last proposition for fig. 8, and we shall have the spheroidal gore required.*

Proposition.—*Problem* 9.

(49.) To describe the gores in order to approximate to the covering of a spherical surface.

Conceive the sphere to be divided into a number of equal parts by planes intersecting each other in one common diameter of the sphere, then each of these equal parts or sectorial solids are contained by three distinct surfaces, of which the figures of two are semicircles, and the remaining one is called a spherical *lune*.

Let a plane bisect the dihedral angle, contained by the two semicircular faces of one of the sectors, and its intersection with the spheric lune will be the semicircumference of a great circle; now let a plane surface be so bent and applied to the spherical lune that every point in the intermediate semicircumference may coincide with the surface thus applied, and if the surface thus applied be cut by the planes of the two semicircular faces, the portion thus intercepted of the surface applied will be a portion of a cylindric surface,† and will be the nearest approximation to the surface of the spherical lune; therefore, to construct a surface which shall be the nearest possible approximation to the entire surface of the sphere, we have only to form the figure of the developement of one of the cylindric parts, which being done, will serve as a mould in drawing the remaining parts, the whole being bent and fixed together so that the vertices may meet, and the adjacent edges come in close contact; then a cylindric polyhedron consisting of as many obtuse angles as there are parts will be formed, and this polyhedron, if the number of cylindric parts be many, will not differ in any perceptible degree from that of the spherical surface.

Fig. 9 exhibits the great circle of the sphere with the divisions, and also the figure of one of the parts in developement; the letters of reference are the same as in fig. 5, which is only required to be understood in order to understand this.

Proposition.—*Problem* 10.

(52.) To find the covering of the surface of a spheroid approximately, the fixed and revolving axes being given.

Because if a spheroid be cut by any plane whatever through the centre, a cylindroidal surface may be so formed and applied to the spheroidal surface, that the two surfaces will only come in contact in every point of the curve of the section of the spheroid.*

---

* *Scholium.* The envelopes of cylindrical, prismatical, conical and pyramidical bodies may be correctly found in one plane figure; but the surface of a nondevelopable solid cannot by any means be unfolded into a plane surface, nor can the figure be altered without breaking it in all parts. Such are the surfaces of conoids which, in course, include those of spheres, spheroids, &c.

† Proposition.—*Theorem* 1.

(50.) All right lines drawn through any given points in the circumference of a great circle of the sphere perpendicular to the plane of that circle, are tangents to the spheric surface at these points, and are in a cylindric surface of which the great circle is a right section.

For, let a diameter of the sphere be drawn perpendicular to the plane of this circle, (which let be called the primary circle,) and the diameter the axis of the primary circle; and let another great circle pass through any one of the given points in the circumference, and through the poles of the primary circle, and let this circle be called a secondary or meridional circle; the circumference of the secondary circle will be divided into four equal parts by the axis, and by the circumference of the primary circle. Now because in any semicircle whatever a right line drawn through the point of bisection in the arc parallel to the diameter is a tangent to the curve at this point; therefore a right line drawn parallel to the axis which is the diameter of the secondary circle of the sphere through one of the points in which the two great circles intersect, will be a tangent to the circumference of the secondary circle at the same point, and since this tangent is parallel to the axis it is perpendicular to the plane of the primary circle. Then, since a right line which is a tangent to a great circle at any point, is also a tangent to the spheric surface at the same point, hence a right line drawn through any given point in the circumference of a great circle of a sphere perpendicular to the plane of that circle, is a tangent to the spheric surface; and as the same may be proved of every right line drawn in the same manner, hence all right lines drawn through any given points in the circumference of a great circle perpendicular to the plane of that circle, being tangents to the spheric surface and perpendicular to the plane of a great circle, are in a cylindric surface of which the great circle is a right section.

Proposition.—*Theorem* 2.

(51.) If two or more great circles intersect a minor circle and intersect each other in one common diameter of the sphere, and if this diameter pass through the centre of the minor circle as its axis, all the tangents to the great circle at the points in which their circumferences intersect the minor circle are tangents to the spheric surface at the same point, and are all in the surface of a right cone of which the minor circle is the base.

For all semi-great circles of the sphere are equal, therefore the semicircles which have the axis of the minor circle for their common diameter are equal; and because the plane of the minor circle will intersect the surface of every semicircle in a right line perpendicular to the axis as an ordinate, hence all the ordinates of the semicircles will be equal, being drawn from the same point in the common diameter; hence all the angles formed by the tangents to the semicircular arcs at the extremities of the ordinates are equal; and because the axis is at right angles with every ordinate, and that the angles formed by the ordinates and the tangents are acute on the side of the minor circle to the nearest pole, and since the tangents and the axis are in the same plane, the tangents will necessarily meet the axis and form as many right angled triangles as there are tangents; but as any one of these right angled triangles has two angles, and the interjacent side respectively equal to two angles and the interjacent side of any other, all the right angled triangles are equal, therefore all the sides opposite to the equal angles are equal; hence all the hypotenuses are equal, and the perpendiculars opposite the angles contained by the ordinates and the tangents are equal; and since they coincide with the axis line, and have one common extremity at the points in which the ordinates intersect, the other extremities will also coincide in a common point; hence all the tangents are in the surface of a cone, of which the base is the minor circle, and the axis the intercepted part of the axis of the minor circle and the conic surface, is a tangent to the spheric surface at every point of the circumference of the minor circle.

The entire ellipse, fig. 10, is a section through the axis of the spheroid, the curve is divided into equal parts and right lines are drawn to the centre; these right lines are the projections of the joints in which the boards meet each other. If every two adjacent lines be prolonged to meet a tangent to the intermediate curve parallel to the chord, the triangles thus formed will be the projections of half the gores. To find the dimensions of the spheroid for any particular gore or part, the semi-axis minor of the spheroid will also be the semi-axis minor of the cylindroid for every gore whatever; and for any particular gore, draw a right line from the centre perpendicularly upon the tangent, or tangent prolonged, and the length of this perpendicular will be the semi-axis major. Thus let the projection of one of the gores be D E F. Prolong E F to C, and draw D C perpendicular to E C, and D C is the semi-axis major. The method of forming the gore is given (48.) and applies here also, the letters of reference being the same in both; the gore being found is here exhibited by the figure E F N A′ M E, as in fig. 8.

Another Method.

(54.) Let the circle A B C H (fig. 11) be a great circle of the sphere, and let C O be a radius of the same. Draw the diameter H B at right angles to A O, and divide the arc C H into a number of equal parts, C d, de, ef, fg, &c., so that the chords may be very small. Draw the right lines dd', ee', ff', gg', &c, parallel to the diameter H B to meet the opposite part of the circumference, and because A B C H is a great circle of the sphere, its plane will pass through the centre. Let the sphere be cut by planes through the points d, e, f, g, &c., perpendicular to the radius C O, and the curved surfaces of the parts will very nearly be the frustums of conic surfaces, and the sections of these solids through the axis are the surfaces comprised by the parallel right line dd', ee', ff', &c. Therefore, if O C be the axis, join dC, then dC is the radius of the sector which will cover the surface of the sphere, of which the triangle cdd' is the projection, or which will cover the surface of the part of the solid of which cdd' is a section through the axis.

Prolong O C to any convenient length, and join dc, ef, fg, &c.; also prolong ec, fe, gh, &c., to meet the prolongation of the axis D C in the points klm, &c.; the right lines ck, dk are equal to the distance of the vertex of the cone to the circumference of each end of the conic frustum, and of which a section through the axis is $dd'e'e$, therefore, from the point k, with the radii kd, ke, describe the arcs dq, er; then the figure $edqr$ is a part of the covering of the surface of the conic frustum of which the section is $dee'd'$. In like manner the coverings of the remaining frustums may be found.*

Application of Cylindric and Conic Surfaces to the Soffits of Doors and Windows.

Def. A soffit is the lower surface, or intrados, of the part of a wall suspended over the aperture of a door or window between the jambs.

We shall treat only of such soffits as are the under surfaces of arches, and those only which are developable, and therefore easily described in plano.

PROPOSITION.—*Problem* 1.

(55.) To find the developement in the construction of a cylindric soffit, perforating a straight wall, so that the axis of the cylinder may be parallel to the horizon, and in any given position in respect of the plane of the surface of the wall, the radius of the cylinder and the thickness of the wall being given.

---

* (53.) For let the section through the centre be called A, and let a section through the axis, perpendicular to the plane of the section A, be called B, and let a third section, parallel to the section B, be called C. Then the sections B and C will be cut by the section A in right lines, which will be parallel to each other, and will be diameters to the ellipses of the sections B and C; therefore since all parallel sections of a conoid are similar figures, and have their corresponding diameters parallel, the tangents at the extremities of these diameters will be parallel to each other. Now every right line which is a tangent to the curve of any section of a solid, is also a tangent to the surface of the solid, therefore the two parallel right lines which are tangents to the curves of the sections B and C, are also tangents to the surface of the spheroid: but the same two points of contact in the curves of the sections B and C, are also points in the curve of the section A; therefore the two parallel right lines, which are tangents to the spheroidal surface, have only their points of contact in the curve of the section A. In the same manner it may be proved that any other right line which passes through any other given point in the curve of the section A, parallel to tangent to the curve in the section B, is a tangent to the surface of the spheroid; hence if these tangents be ever so numerous, being all parallel, they are in the surface of a cylindroid, which will touch the spheroidal surface only in every point of the curve of the section A.

Scholium. Another method of finding the coverings of solids of revolution, is by supposing in any such solid that it is divided into a great number of parts by planes perpendicular to the axis of rotation, so that the chords of the curb surface may be all equal and very narrow, the spherical surfaces of the frustums will not differ sensibly from the surface of the frustums of right cones which are developable. Now as the covering of every right cone is the sector of a circle, of which the radius is equal to an edge of the cone, and the length of the arc of the sector equal to the circumference of the base of the cone, and because similar cones have their angles of developement, that is the angles of their sectorial coverings equal; and since the frustum of a cone is the portion of a cone that remains after cutting off the part next the vertex by a plane parallel to the base, and as the part thus cut off is a cone similar to the whole cone.

Therefore, if the angle of developement of a right conic surface be found, the truncated sector which will cover any given frustum of this cone will be found, by describing, from the vertex of the angle of developement, with radii respectively equal to an edge of the whole cone and equal to an edge of the part cut off, two arcs, then the four-sided figure contained by the two arcs, and the portions of the right line forming the angle of developement intercepted by the arcs, is the covering required.

But, since the edges of a right cone are equal, any edge of such cone is equal to the hypotenuse of a right angled triangle, of which one of the legs is equal to the axis of the cone and the other equal to the radius of the circular base; therefore, in order to find the radius of the sectional covering from the given cone, we have only to construct such a triangle, or two such triangles being joined so that they may have a common leg equal to the length of the axis, will form an isosceles triangle, of which the hypotenuse will be the equal sides, and the two remaining legs will be equal to the diameter of the circular base.

The isosceles triangle thus constructed will be equal to a section of the cone through its axis. We shall now apply the principles of describing the covering of cones, or of their frustum, to the coverings of spherical surfaces.

* These methods of covering a spheric surface may be distinguished by the names of the cylindrical and conical principles, as in the former case we approximate to the spherical surface by means of cylindrical surfaces, and in the latter we approximate to the spherical surface by means of conic surfaces; the conic method is the most easy in its general application, the principle is the same whether the solid be a sphere or a spheroid or conoid, so that the solid may be divided by planes perpendicular to the axis of rotation. The conic method, however, requires more materials to cover the solid than the cylindric method; and in the most useful solid, which is the sphere, its application is abundantly easy; since when one figure is formed, the remaining ones may easily be described without constructive lines, only employing that which was found by a construction as a mould.

Let the parallel right lines B C, A D (fig. 12) be the intersections of the faces of the wall, with a plane parallel to the horizon. Draw the right line B A so that the angle C B A may be equal to the angle which the axis of the cylinder makes with the plane of the wall, and prolong A B to any convenient point E. Draw E G perpendicular to A E, and make E G equal to the diameter of the cylinder. Draw G D parallel to E A, meeting B C in C, and upon E G as a diameter describe the semicircle E H G. Prolong G E to I, and make E I equal to the developement of the semicircular arc E H G. Divide the semicircular arc E H G and its developement E I each into the same number of equal parts, and draw right lines through the points of division in the semicircular arc to meet the base E G. From the points of section in E G draw right lines parallel to G D or E A, to intersect B C and to meet the right line A D, and from the points of division in E I draw right lines also parallel to E A, and consequently perpendicular to E I. Find points in the parallels drawn from the points in E I by transferring the parallels comprised between the right lines E C and E G, so that the distances as they recede from A E on each side of it may be respectively equal, and through the points of division marked upon the parallels draw the curve K L B. In the same manner find the curve M N A and join K M, then K L B A N M is the developement of the cylindric intrados or soffit required.*

Def. A surface is said to be perpendicular to a plane when a right line, drawn from any point in the intersection or trace of the surface perpendicular to the plane, coincides in all parts with the surface.*

PROPOSITION.—*Problem* 2.

(56.) The plane of a circular wall being given, the radius of a cylindrical soffit, and the direction of the axis of the cylinder in a horizontal plane, to describe the developement of the soffit.

Let A E C and B F D (fig. 13) be the plans of the faces of the walls, and let them be parallel arcs of circles; then the two faces of the walls will be concentric, cylindric surfaces having their axis perpendicular to the plane of the horizon, that of the aperture being parallel to the horizon. Let G F be the direction of the cylindric surface of the aperture passing through the axis of the faces of the cylindric wall. Draw A B and C D each parallel to G F, and at a distance from G F equal to the radius of the cylindric soffit, and draw the chord C A of the arc of the concave side of the plan of the wall. Then A B F D C may be supposed to be a horizontal section of the cylindric part of the intrados of the arch through the axis upon which the soffit is to be formed. Upon A C as a diameter describe the semicircle A H C, and prolong C A to I. Make A I equal to the developement of the semicircular arc A H C, and divide the arc A H C and the right line A I, each into the same number of equal parts.

Through the points of division in the arc A H C draw right lines perpendicular to A C to meet it in as many points as the perpendiculars are in number; and from all the points of section in A C draw right lines parallel to A B, intersecting the curve A E C, and meeting the curve B F D each in as many points as the number of lines which are parallel to A B, drawn from the points of section in A C. Through the points of division in A I draw right lines parallel to A B, and upon each of these right lines receding from A set off the respective distances comprised between the chord A C and the curve A E C. Through the extremities of the distances draw the curve I K A, and, in the same manner, draw the curve L M B, and join I I; then the figure A M B L I K A is the developement of the soffit required.*

---

* In order to prove the truth of this, it is only necessary to show that the developement will, when properly bent, coincide with the cylindric surface, and its edges with the two planes which are perpendicular to the plane of the axis of the cylinder, and which are the faces of the walls.

The following are the propositions in which the demonstration depends, *viz.*

Every right line which is parallel to the plane of projection, is projected into a right line equal to its own length.

Every right line and its projection are in a plane perpendicular to the plane of projection.

Every point which has a projection is in a right line perpendicular to the plane of projection drawn from the projection of the point.

Now, since the plane of projection contains the axis of the cylinder, and all the right lines on the curved surface of the cylinder are parallel to the axis, therefore all right lines upon the surface of a cylinder are projected upon a plane which contains the axis, into right lines of equal length and also parallel to the axis.

Let the plane of the semicircle E H G be raised upon the right line E G perpendicular to the axis, and suppose the semicylinder to be placed upon the section so that the axis may be upon F B, and the centre of the semicircular base upon the point F; then the semicircumference E H G will coincide with the semicircumference of the end or base of the cylinder.

Then, because if in the plane of developement two right lines form a right angle, and if one of them be applied so as to coincide with any edge of a cylinder, and if the plane of developement containing them be bent upon the cylindric surface so that all the points of the two surfaces shall coincide, then the other right line will fall upon the circumference of a circle which will be a right section of the cylinder.

Moreover, if two right lines in a plane are parallel, and if one of these right lines be applied to any edge of a cylinder, and the plane so bent upon the cylindric surface that all the points of the two surfaces may coincide, then the other right line will coincide with another edge of the cylinder.

Therefore, in the developement, since the right line E I is the length of the semicircular arc, and both the right line E I and the semicircular arc divided into the same number of equal parts, and since the right line E I is perpendicular to the edge E B of the cylinder, therefore if the developement A E I M N A be bent upon the cylindric surface, and if all the points in both surfaces be in contact, the right line E I will fall upon the arc of the semicircular base, and the points of division upon the corresponding points of the semicircular arc, and all the right lines which were in the developement will be parallel right lines upon the cylindric surface, and will therefore be parallel to the axis; and as these right lines pass through points in the circumference of the base, and as those points in the circumference of the base are the upper extremities of right lines perpendicular to the plane of projection, and the other right lines drawn in the plane of projection from the foot of the perpendicular are parallel to the axis; hence the right lines upon the cylindric surface drawn from the upper extremities of the perpendiculars, and the lines drawn from the feet of the perpendiculars in the plane of projection, are in planes perpendicular to the plane of projection, *viz.* every two which are drawn from the same perpendiculars are in a plane perpendicular to the plane of projection and parallel to the axis of the cylinder; hence the right lines which are drawn in the plane of projection parallel to the edges of the cylinder, are the projections of the right lines which form the edges of the cylinder, and, since all the points of these edges are equal to the corresponding parts of their projections, all the points in the plane of projection must be the projections of the points upon the cylindric surface; and as the curves pass through these points in the cylindric surface and the right lines which form the faces of the wall pass through, the points in the plane of projection; therefore, the whole developement will coincide with those lines on the cylindric surface of which the projections are given.

* *Scholium.* The following theorems are indispensable, and are almost self-evident of themselves; but, as the last two require many words to connect the chain of reasoning, we shall be under the necessity of omitting the demonstration, and so remain satisfied with the enunciations of the propositions.

Proposition.—*Problem* 3.

(59.) To draw a tangent to either of the curves in the developement of a cylindrical soffit in a straight wall, the axis of the cylinder being parallel to the horizon, but oblique to the face of the wall.

Let it be required to draw a tangent at the point L (fig. 12) in the curve K L B. Draw L s parallel to A E, meeting E I in s, and make the arc E r equal to the right line E s. Draw $r v$, a tangent to the semicircular arc E H G, at the point r; and from any convenient point, v in $r v$, draw the right line $v t$ perpendicular to A E, meeting I E in t. Draw $t u$ parallel to B C, and $r z$ perpendicular to E G, meeting E G in z; also draw $z u$ parallel to E A. Construct, in any convenient situation, the right angled triangle $x y w$, so that the base $x w$ may be parallel to E I and equal to $v r$, and that the perpendicular $x y$ may be equal to $z u$. Through the point L draw J Q parallel to $y w$, and J Q is the tangent required.

Proposition.—*Problem* 4.

(60.) To draw a tangent to either of the curves in the developement of a cylindric soffit in a cylindric wall, the axis of the cylindric surfaces being in the same plane, one parallel and the other perpendicular to the horizon.

This process is in every respect the same as the preceding, except that a tangent must be drawn to a corresponding point in the curve of the plane of the wall; and then the tangent to be used in the same manner as was done in respect of the right line B C. (Fig. 12.)

Let it be required to draw a tangent through the point K (fig. 13) to the curve I K A, which is the developement of the cylindric soffit, and the concave face of the wall. Having drawn $r z$ perpendicular to A C, draw z E parallel to A B, meeting the concave side of the plan of the wall in E; and through the point E draw P Q, a tangent to the circular arc A E C, which is the plan of the wall. Then, having constructed all the parts, and the triangle $x y w$, as in the preceding problem, through K draw J N parallel to $y w$, and J N is the tangent required.†

PRACTICAL CARPENTRY.

Section I.

The practical operations in Carpentry consist in the methods of preparing timbers and in joining them together, so as to effect the end or purpose desired.

Junction of timbers.

Timber bars may be extended to any length in a right line, by joining one timber to the end of another as often as may be necessary to make the required length, by cutting the corresponding ends which join, in such a manner that every point of the part cut away in the one will coincide with a corresponding point in the other; in whichever of the two the point is taken. The parts cut away at the two ends of two pieces of timber which join are generally plane surfaces, and the joint ought to be such, that when the two timbers are joined and kept together, two forces applied in a direction of the length of the two pieces thus united, may not be able to pull them asunder without breaking at the joint. Timbers joined in the manner now described are said to be *scarfed*. This will be evident by inspecting figures 13 and 14, which are the simplest forms of scarfing.

Scarfing.

Fig. 13 exhibits a plane scarfing, and fig. 14 a scarfing put together with two wedges in such a manner as to draw the joint close together The timbers of fig. 14, if held together sideways, without any pressure but that which is just sufficient to keep their surfaces straight, could not be drawn from each other, when keyed or wedged, without splitting off some part or other at the joint.

Timbers may also be joined either at oblique or at right angles. The timber bars which form the enclosure of every frame used in building may be rectangular, excepting those which are employed in the different faces of a roof in order to support the covering. There is no reason, however, why the interior timbers of every frame comprised between the sides of the enclosure should not be rectangular. The advantage of rectangular bars will appear manifest from the following consideration: if two rectangular bars have each two faces perpendicular to a plane, and if the two faces of the one which are perpendicular to the plane intersect the two faces of the other which are perpendicular to the same plane, two intersections of these faces will be perpendicular to that plane.‡

Whenever two pieces of timber are joined to form an angle, we shall always suppose that they are rectangular bars, of which two faces are parallel to a plane, and

---

Proposition.—*Theorem* 1.

* (57.) If a plane A, and any surface B, be each perpendicular to a plane C, the common intersection of the plane A and the surface B will be a right line perpendicular to the plane C.

Proposition.—*Theorem* 2.

If any right line be drawn parallel to the edge of a plane, which is also a right line, and if the plane be so bent that, when applied to a cylindric surface, the rectilinear edge of the plane may coincide with an edge of the cylindric surface, and the bent surface in all points with that of the cylinder, the other line upon the bent surface will fall also upon an edge of the cylinder, or coincide in all points of it.

Proposition.—*Theorem* 3.

(58.) If in any plane A, passing along the axis of a cylinder without the solid, a point B be so situated that the shortest distance to the nearest edge C of the cylinder may be less than the circumference, and if a right line D be drawn in this plane through the point B perpendicular to the axis; and if the plane be so bent into a curved surface E, and applied upon the cylindric surface, that all the points of the two surfaces may coincide, the position of the point B in the bent surface E will be in another plane F, passing along the right line D perpendicular to the first plane A.

† *Observation.* As the first of these curves in Prob. I. fig. 12, of this section is the developement of the intersections of the surfaces of a cylinder and that of a plane, the method of drawing the tangents to the intermediate points of the curves in fig. 5, 6, and 7, being of the same species, will be the same as here shown. It will only be necessary to give an example of the method of drawing a tangent to the extremity of the curve, fig. 5. In A′C make A d equal to D C, and draw $d e$ perpendicular to A C. Make $d e$ equal to C E, and join A e. Then A e is the tangent required. This description will also apply to fig. 6 and 7.

‡ The trusses of a roof are the only frames in a building comprised between parallel planes which have not to support a covering, their office being to support the weight of the roof which presses upon their sloping edges. All timbers in the truss of a roof ought to have each two faces parallel to a given plane, and the other two faces perpendicular to that plane, in order that when they join, the intersections of the faces which are perpendicular to the plane may be in right lines perpendicular to the other two faces.

consequently the other two faces perpendicular to that plane, unless the contrary is expressed; and thus, when one piece of timber is perpendicular to another, if the end of the one piece fit close upon the side of the other, that end must be in a plane perpendicular to any one of the four arrises of that piece.

Every timber in a building which terminates with a close joint upon the face of another, will have its end in the figure of a rectangle, of which two sides will be perpendicular to the plane of the angle formed by these two timbers, except in the faces of hip or in hip and valley roofs, where the ends of the jack rafters and the ends of the purlins meet the hips.

When the ends of a piece of timber join one of the faces of another piece of timber, and form such a joint that all the faces of the piece of which the ends fit upon the other intersect, and form a close joint, these two timbers may be firmly secured to each other by means of nails or bolts, provided that the angle which they form is very oblique. This form of joint is called a *shoulder joint*, and the end of the piece which fits upon the face of the other is called the *shoulder*: but if the directions of the pieces form a right angle, or approach nearly to a right angle, such a method of fixing them cannot be secure, at least where one of them acts as a lever upon the other.

Shoulder joint.

Another method of fixing two timber bars at a given angle, is to cut the ends of each of the pieces, so that they may meet each other in a plane perpendicular to the plane of the angle which the two pieces make with each other, and which will either bisect that angle or pass through the intersections of the outer and inner faces of these timbers. This form of joint is called a *mitre joint*, and the two pieces are said to be *mitred*. Here the lengths of the mitring surfaces in both pieces are equal. The pieces which are mitred together may be rendered much more secure by means of nails or bolts, than when they are simply shoulder jointed, particularly when one of the pieces is required to act as a lever upon the other.

Mitre joint.

One piece of timber may be joined to another by inserting a part of the one into an excavation of the other, or reciprocally by excavating both, and inserting a portion of the solid of the one into the hollow of the other. The surfaces which are thus concealed by being brought into contact are called a *close joint*. A close joint may be made in an infinite variety of ways; by making the hollow of the one in such a manner, that when the two pieces are joined all the points of the surface which were excavated in either piece may come in contact with some point or other of the surface of the other solid. This is an universal method of joining timbers, but the modes by which it may be done are of infinite variety. Generally, whatever may be the office of a piece of timber which is to be fixed to another, the excavation which is cut in the one piece in order to receive a part of the solid of the other, ought to be such that the surfaces may be in planes either perpendicular or parallel to the face of the timber from which the excavation may be made. The particular manner of forming the joint will depend upon the two following cases; *viz.* 1, when one of the pieces is fixed and the other in a state of tension; and 2, when one is fixed and the other in a state of compression. As every timber bar has a considerable weight, it cannot be kept stationary without being supported at least under one point; but the most secure supports will be under its extremities. For whatever be the kind of pressure to which a bar of timber may be subjected, it has also to support its own weight; and thus the formation of the joint of two timber bars to be fixed to each other at a given angle will depend upon the joint consideration of the species of strain and the weight of the timber.

Close joint.

In forming the joint of two timbers making a given angle with each other, we shall always suppose that one of the pieces is fixed or immovable by some means or other, and the species of strain to which the other may be subjected given, and that the fixed piece has to support the other.

The case of tension requires the joint to be made in such a manner, that it would be impossible to pull the piece of which the strain is given out of the fixed piece without leaving a part of the end of the one or the other or of both timbers. The operation of forming such a joint has been called *cocking*, and the piece of timber in the state of tension is said to be *cocked* upon the other.*

Cocking.

When two pieces of timber are of the same thickness, and are required to be joined to each other in the form of a cross, the two parts may be so cut, that when put together they may be comprised between two parallel planes at a distance from each other equal to the thickness of one of the pieces only. This method is called *notching*, and when each of the pieces is reduced to half its thickness, by taking away a rectangular solid equal to half their thickness, the method of notching is called *holving*.

Notching.

Holving.

When two timber bars are intended to be joined together in order to form a cross, where one of the pieces is to be let down upon the other, two notches are generally cut from the upper face of the lower bar, by taking away two rectangular solids, and leaving a solid part between the two notches, and one notch is cut from the lower face of the upper bar to fit the piece which remains whole between the two notches in the lower timber bar, so that when the two timbers come to be joined, two ends of the two notches of the lower piece, and one of the perpendicular faces of the upper piece, may be in the same plane, and the remaining ends of these two notches in the lower bar in the same plane as the remaining opposite perpendicular face of the upper bar, and that the depths of the notches in both pieces may be equal to the distance intended to be let down.

---

* The state of compression requires only that the end of the timber may be supported from falling, and that it may coincide in all parts with the face of the fixed timber: therefore any joint that will answer this purpose will be sufficient.

Another consideration in the joining of two timbers A and B together is, 1. when the length of the timber A extends from one of the perpendicular faces of the timber B to any required distance before the opposite face of B, and reciprocally when the length of the timber B extends from one of the perpendicular faces of the timber A to any required distance before the opposite face and thus making two arms which form only one angle.

2. When the length of the timber bar A extends from one of the perpendicular faces to any required distance before the opposite perpendicular face of B, and when the length of the timber bar B extends on both sides of the timber bar A, without dividing it into two parts, and thus making three branches which form two adjacent angles.

3. When the length of the timber bar A extends on both sides of the timber bar B, and the length of the timber B on both sides of A, without dividing either of the timbers A or B into separate parts, and thus making four arms or branches, of which every two will make the opposite angles equal.

The first of these modes is the weakest, the second is stronger than the first, and the third is stronger than the second, and consequently the strongest of the three. In the first, one is said to form an angle with the other, and is called the method of joining at an angle; in the second, one timber is said to stand upon the other, and is called the method of joining at two adjacent angles; and in the third, either timber extends on both sides of the other, and is called the method of the cross.

In plate iii. fig. 15, the figure *e f g h*, No. 1, is a right section of the lower timber; A B C D one of the vertical faces of the upper timber. These exhibit the manner in which the solid part between the two notches of the lower timber fills the notch in the lower side of the upper timber. In No. 2, S T U V exhibits a part of the upper face of the lower bar, with the outlines *i j k l*, *m n o p* of the notches, *w x r q* show the situation into which the upper timber comes.*

Though fig. 15 and 16 are essentially the same in principle, fig. 15 is adapted to the cockings of roofs and floors upon wall plates. Here, as each extremity of a beam must be within the thickness of one of two opposite walls, and the two opposite wall plates are each in the plane of the two interior faces of the two walls, the length of the beam cannot therefore extend over the outside vertical surfaces of each wall plate in any considerable degree, perhaps not more than the breadth of the wall plate itself, if rightly proportioned to the thickness of the wall. In this case the weight of the beams alone, independently of the weight of the incumbent parts of the wall, gives sufficient pressure to keep them in their cockings when they are either pulled or compressed. This is the reason for diminishing the breadth of the solid break *k l p o*, between the two notches in No. 2, fig. 15, and keeping nearer the face in the interior surface of the wall than to the other vertical face inserted in its thickness.†

Though, as has already been observed, fig. 15 and 16, plate iii., are the same in principle, yet with respect to their use, they are adapted to very different purposes. It has been shown that fig. 15 is adapted to the juncture of the tie beams of a roof to the wall plates, and it will now be shown that fig. 16 exhibits the best proportion between the tongue part of the joint, and the notches where the two pieces of timber are joined in the form of a cross in which the upper timber extends before the lower vertical faces to a considerable distance. In this case, as each arm of the upper timber extends before each adjacent face of the lower timber, there can be no danger of splitting away the part between the notch and the extremity; hence the breadth of the tongue *k l p o* between the two notches of the lower piece may be made in the middle of the breadth of the upper face of the lower timber, and of much greater breadth than that in fig. 15, so that each of the two notches in the upper face, No. 2, fig. 16, will be much narrower than the width of the notch *i j k l*, fig. 15; by this means the strength of the piece S T U V, fig. 16, will not be sensibly diminished by the two notches.*

Indeed, if the bridging joists were merely laid upon the binding joists without any notching whatever, the floor would be equally strong as if they had been notched. The only use, therefore, of notching and tonguing is to give the bridging joists a more steady bed upon the binding joists; and this would often be required when the binding joists are bent in the seasoning of the timber, or by taking a curved direction after the operation of sawing.

The proportion between the breadth of the tongue and that of the notches, and the situation of the tongue in regard of the horizontal breadth of the timber, from which it is cut, is not only applied to the joinings between the bridging and binding joists in floors, but also to the joinings between the common rafters and purlins, and between the purlins and principals in roofing.

Fig. 17 exhibits another distinct method of cocking wall plates upon tie beams by dovetail joints. But by this method of forming the joint between two timbers, when the upper timber shrinks the dovetail tongue at the end will also shrink; and thus the joint will open. And hence in the case of an extending force, the upper piece will be liable to be drawn away from the lower piece; but this cannot be the case when the tongue of the lower piece runs across the breadth of the upper piece, and its being made so very narrow leaves but a very small breadth for shrinkage.[*]

---

* It is now evident that if the lower bar S T U V were immoveably fixed, and the upper timber bar *w x r q* were kept down upon the lower timber bar S T U V by any sufficient pressure, that it would be impossible to draw the upper bar from the lower one, by any force pulling in a direction of its fibres; but when one of the arms of the upper timbers extends only a very short distance from the adjacent vertical face, as in fig. 15, the part *w x k l* of the short arm underneath, between the notch and the extremity, would be liable to split off: for this reason, the solid part *l k o p* is not only made narrower, but brought nearer to the face adjacent to the long arm, than if both had been long arms, as in fig. 16.

† It cannot be properly said, that when timbers are perfectly straight, any timber bar is either drawn from or compressed towards the wall plate, because the ends of the bar only lie upon the wall plates, and therefore their weight only presses perpendicularly upon them. However, as all timber is liable to bend, and if it bend by not being sufficiently strong, the under edges of the beams will descend from each extremity to the middle in a curve, and will therefore form a wedge, which will endeavour to separate the two opposite walls to a more remote distance, in this respect these beams will be actually drawn in a direction of their tangents to the extremities of the curves upon the under edges of the beams; and not only from this circumstance alone, but even by the walls themselves having a tendency to separate, from being unequally supported at the foundation, or from bad building, by which the walls may contract more upon one side than upon the other. To verify these observations, many floors have fallen down, and this could not have happened unless by the spreading of the walls. There is not so much danger to be apprehended from the tie beams of a well-constructed roof having any tendency of being drawn from the wall plates, as from the binding joists of a floor; for the tie beams may be kept in a right line by being supported in a sufficient number of points, so as to divide the length into equal intervals of short bearings: moreover, the weight of the roof is discharged upon the tie beams in two different directions from each end, so that in each end one direction is perpendicular to the horizon, and the other is parallel to it. The tension of the tie beams is sufficient to resist the force of extension without making any sensible alteration in their length; therefore the only effect which the roof can have, is a perpendicular pressure upon each wall equal to half its weight. The case would be very different if the ends of the principal rafters were supported by the wall plates, instead of being supported by the ends of the tie beams; for if the principals were supported by the wall plates, the wall plates would have a tendency to separate from each other, and nothing could prevent this separation except the cockings at the ends of the tie beams.

* This proportion and situation of the tongue, in respect of the breadth of the upper horizontal face, in which it is situated, as shown in fig. 16, is proper for one of the joints between a bridging and binding joist, as the area of the right section of the binding joist is not diminished in any considerable degree. This case, as the binding joist is only supported by opposite walls, or between a girder and the wall, or between two girders, requires the binding joists to be of the greatest possible strength, and differs materially from the other case, in which the wall plate is in the same situation in respect of the binding joists as the binding joist is with respect to the bridging joist; and in the mode which fig. 15 exhibits, the wall plate is supported in every point by the stone or brick work underneath, which is levelled for the purpose of receiving the lower horizontal face of the wall plate; but as to the binding joist it is quite unsupported except at its extremities, and therefore the less the substance is diminished in any part the resistance which it makes will be greater. If the binding joists are sufficiently strong, any moderate pressure laid upon its middle will not have any sensible effect in drawing the bridging joists, between which it is suspended.

Mortise.

Tenon.

A *mortise* is a recess in the figure of a prism from any face of a piece of timber to any depth, or even entirely through the timber, and a *tenon* is a part left on the end of a piece of timber, proceeding forward generally from a plane surface in the form of a prism, so that one of the parallel ends may be in the plane from which the tenon proceeds, and the other end the extremity of the tenon, and that the remaining faces of the tenon may be parallel to the faces of the timber from which the tenon is made. The apparent part which forms a border round the tenon is called the *shoulder* of that tenon.

Shoulder of a tenon.

One piece of timber may be joined to another by means of a mortise and tenon adapted to each other so as to have a close joint; hence the shoulder of the tenon will coincide with the face of the other timber from which the mortise is recessed, and because the timbers are generally rectangular bars, and when one bar is joined to another, the tenon if cut through in the same plane with the shoulder will be a rectangular parallelopiped. The manner of joining rectangular bars by means of a mortise and tenon is of excellent use where it is required to confine a piece of timber between two others which are firmly supported, and the piece between only to be supported by these timbers, considering it either in a state of compression, or by being strained transversely by a force.[†]

SECTION II.

A frame consisting of timber bars so constructed that every bar may be divided longitudinally by a plane into two symmetrical parts, and that the section of the frame made by this plane may also consist of two symmetrical parts on each side of a right line perpendicular to the section of one of the outer edges called the base; moreover, that if two extremities of the base be supported, and if forces be applied so as to act at certain other points upon the surrounding edges of the frame in the bisecting plane, and in right lines perpendicular to the base, and that the number of these points on the one side of the perpendicular may be equal to the number of points on the other side, and that every pair of such points may be in right lines parallel to the base, and equally distant from the perpendicular, and that the forces upon every two corresponding points may be equal, and that the effects of these forces may not have any tendency to produce a transverse strain on any part of the frame; such a frame is called a *truss*.

Truss.

Points of suspension.

Truss points.

The two fixed points, one at each extremity of the base, are called the *points of suspension*, and the remaining points, on which the forces act so as to keep the frame in equilibrium, are called *truss points*.

Plane of the truss.

Line of symmetry.

Plane of symmetry.

The plane which bisects the timbers is called the *plane of the truss*, and the perpendicular which divides the truss into symmetrical parts is called the *line of symmetry*; moreover, a plane passing along the line of symmetry perpendicular to the plane of the truss is called the *plane of symmetry*; and thus the plane of symmetry divides the truss into two equal parts.[*]

Each of the two points of suspension of every truss is in the under horizontal face of the tie beam, near the extremity of that face, and rests immediately upon the wall plate.

The tie beam of every truss in a roof ought to be supported in a certain number of equidistant points, so that if weights are suspended from these points, the weights thus suspended would not cause a transverse strain in any timber whatever in the construction of the truss.*

---

[*] The method of rectangular notches, and a rectangular tongue, of which the apparent sides are parallel to the sides of the timber, is of very late introduction, perhaps not more than sixty years. The principle of notching with square abutting joints, has always been much adhered to by the best Carpenters since its first introduction: but its advantages over the dovetail joint in not admitting the upper piece to be drawn out of the lower piece when the timber is shrunk, was, we believe, first noticed by Mr. Peter Nicholson.

[†] The method of joining two timbers by means of mortise and tenon is that which is applied to the trusses of roofs at the joggles, and in fitting the upper ends of the struts into the inner or under edges of the principal rafters. This mode is also frequently applied to truss partitions, similarly to its application in the trusses of roofs; moreover, the joining of timber bars by means of mortise and tenon is also applied in naked flooring in connecting the trimmers to the trimming joists, as also, with a slight modification, to connecting the binding joists with the girders. The only difference in this application from common mortise and tenon being in the shoulder of the tenon, in which the upper part is made to slope towards the tenon in such a manner, that the upper surface of the tenon and the part of the shoulder above it may form an internal obtuse angle, equal to the external angle made by the same part of the shoulder of the tenon and the upper horizontal surface of the binding joist. This sloping part of the shoulder of the tenon upon the end of the binding joist is called *tusk*, which is let into the girder with a view of giving a stronger support to the tenon, which is generally made thin in order to preserve the substance of the girder as much as possible.

The method of connecting the ceiling joists with the binding joists is a species of mortise and tenon. In the ceiling joists the shoulder of the tenon is generally made adjacent to the under horizontal surface of the ceiling joist, only so that the upper horizontal surface of the ceiling joist and that of the tenon may be in one plane. The tenon formed in this manner is called a *barefaced tenon*. But as the ceiling joists are generally put in after the building has been roofed, and as in this case the binding joists are always fixed, their ends being inserted in the opposite walls, or between two girders, or between a girder and the wall, the mortises must be prepared in such a manner as will admit of the ceiling joists being brought to their places, as if they had been previously formed, into the placing of the binding joists on the building.

To fix the ceiling joists under these circumstances; the mortises must be prepared in such a manner that if we call a close mortise at one end *m*, and at the other end M, and one of the two next adjacent mortises from the same face N; when the tenon is fitted into the mortise *m*, the other tenon when revolved round *m*, as a centre, may find no obstruction in bringing it to its place M, where it cannot be moved further in any direction except backwards. This may be accomplished by cutting away as much of the binding joists which contain the mortises M and N as may be necessary; and this is generally done by cutting away the wood below the mortise M so as to make one long mortise instead of the two M and N, the sides and back of the long mortise being a continuation of the planes of the sides and backs of the mortises M and N. The long mortises which are thus cut in the vertical sides of binding joists are called *pully mortises*, or *chase mortises*.

[*] The definition which we have given of a truss is such as will be found to apply in many situations; *viz.* in roofs to support the inclined covering; and here also it may be employed in discharging the pressure of the rafters from the intermediate parts of the walls in case that the roof is constructed without tie beams. Trusses are also used in partitions for supporting the floors.

When a truss is employed for supporting the covering of a roof, the bisecting plane of the timbers ought to be in a plane perpendicular to the plane of the roof and in a plane perpendicular to the horizon, and thus the rafters and tie beams will be perpendicular to the wall plates; and when a truss is employed for discharging the pressure of the rafters from the wall plates, and consequently from the walls themselves, the plane of the truss ought to be parallel to the plane of the covering.

If a truss be so constructed that when the line of symmetry is perpendicular to the horizon, and the whole of the timber work situated above the horizontal line; then if in the half of the truss upon one side of the roof, the upper ends of the remaining timbers of the surrounding enclosure be nearer to the line of symmetry than the lower end, such a truss is proper for the truss of a roof.

In the application of trusses to roofing, the truss points will be in the upper inclined edges of the principal rafters, and they ought to divide the lengths of their rafters into equal parts, so that every truss point may support a point of a purlin, and all the truss points in the inclined upper edge of the principal rafter will support one point of every purlin, and all the truss points will support all the equidistant points of every purlin.

Trussing post. King post. Corresponding side posts. Queen posts. Tie beam.

Every timber bar which forms one side of a triangle, and which is perpendicular to the horizon, is called a *trussing post.* A trussing post in the middle of a truss is called a *king post.* Two trussing posts on each side of the plane of symmetry, and equidistant, are called *corresponding side posts,* and if there be only one pair of corresponding side posts in a roof, such a pair of side posts are called *queen posts:* moreover, if the truss posts consist of more than one pair of corresponding side posts, but have king posts, that pair of corresponding side posts which are at the least distance from each other are called *queen posts.* If a truss have only one beam, that beam is called a *tie beam;* but if it have two beams, the lower beam is called the tie beam, and the upper beam is called the *collar beam.* If the principal rafters are supported upon an independent truss, the timbers in the truss upon which the principal rafters are supported are called *auxiliary rafters.*

Collar beam. Auxiliary rafters.

Fig. 18, pl. iii. is the elevation of a truss which exhibits the faces of the timbers which are parallel to the plane of the truss, and in their real proportions, T t being the tie beam, P p, P p the two principal rafters, K k the king post; D d, D d queen posts, B b collar beam, E e, E e auxiliary rafters, and S s, S s struts. These are the timbers which constitute the truss. The truss is supported by the wall plates, of which their sections are W, W, fig. 18. The timbers supported immediately by the truss are the pole plates Q q, Q q, fig. 19, the purlins L l, L l, and the ridge piece R r, and lastly, the timbers supported by the pole plates, purlins, and ridge piece are the common rafters, C c, C c. The double letters in the timbers supported by the truss, are only to be found in the perspective view, as also in the wall plates W w, W w.

SECTION III.

To find the lengths and angles of the timbers of a roof in every position in which they can be placed, is only to resolve the various cases of the right trehedral. It may be proper to observe in this place that those who have previously acquired this knowledge will never be at a loss to solve every difficulty; but those who have not done so, must be contented with the rules by which the particular case in hand may be constructed. We shall here give an example or two of the application of the trehedral, which perhaps will be as much as the practical Carpenter may desire, but which will be of signal advantage to the theorist by showing how the principles are applied in practice.

Example 1. Given the directions T U, U V, V W, fig. 20, pl. iii., of the wall plates of the regular hip end of a ridge roof single inclined upon each side of the ridge piece, and the height of the roof, to find the lengths of the common and hip rafters.

In U T and in V W make U d and V a each equal to the half of U V, and draw the right line $a\,d$. Bisect $a\,d$ in c, and draw $c\,b'$ perpendicular to $a\,d$. Make $c\,b'$ equal to the height of the roof, and join $a\,b'$, $b'\,d$, and $a\,b'$, $b'\,d$ are the lengths of the common rafters.

From a with the distance $a\,b'$, the length of a common rafter, cut $a\,d$ in b, and join V b, and V b is the length of the hip rafter.

Example 2. To find the angles of the backs of the hip rafters.

Join V c, and through any convenient C in V c draw B e perpendicular to V c, meeting V W in B and V U in e. Draw B A perpendicular to V b, meeting b V in A, and from the point B with the distance B A cut c V in A'. Join A' B and A' e and B A' e is the entire hip angle, or the angle of the back of the hip rafter.*

Example 3. The same things being given to find the angles which the upper arrises of a purlin makes with each adjacent arris of the section of that purlin upon the vertical face of the hip rafter.

In $b'd$, the back of the common rafter, let $f\,g$ be the side of a right section of the purlin, and $f\,g\,h\,i$ the entire right section. Join c U, and draw $f\,o$ parallel to U T meeting U c in o. From the point f with any convenient radius describe the semicircle $j\,l\,m\,k$, and draw the diameter $j\,k$ parallel to $d\,a$. Let the semicircle cut $b'\,d$ in l and $f\,i$, prolonged if necessary in m. Draw $j\,r$, $l\,s$, $m\,q$, and $k\,p$ parallel to $f\,o$, and let $l\,s$ and $m\,q$ meet c U in s and q. Draw $q\,p$ and $s\,r$ perpendicular to $f\,o$, and join $o\,p$, $o\,r$; then $n\,o\,r$ and $n\,o\,p$ are the two bevels required.†

The developement or the method of extending the surfaces of a roof in planes are of signal utility in finding the lengths and bevels of all the timbers in these various faces.

Example 4. To describe the covering of a regular hip roof in plano, the plan of the roof being given.

Part 1. Let A B C D, fig. 21, be the plan of the edges of the wall plates, E F the plan of the ridge. From any convenient point E in E F draw E *g* perpendicular to one of the sides of the planes A D, and in E F make E *h* equal to the height of the roof, and join *g h*. Draw E *e* perpendicular to A D intersecting A D in *g*, and make *g e* equal to *g h*, and join A *e*.

---

* The number of trusses in a roof will depend upon the length of the purlins in their extension from gable to gable, or from hip to hip or from hip to valley. The truss points in a roof may be found so that the rafters may be equally divided, or in given proportion, by timbers so arranged as to form two series of triangular openings between the points of suspension, so that the vertex of every triangle of one of the series may be in the under inclined side of the principal rafters, and that the opposite side may meet the vertices of two adjacent triangles of the other series of which the bases are parts of the principal rafter.

* *General observation.* The part of the first example which shows how the length of the hip rafters are found, is the same case of the right trehedral as when there are given the inclination and the adjacent right face to find the oblique face. (7.) Here a V c is the adjacent face, and V a the adjacent edge. Then having assumed the point a in V W, draw $a\,c$ perpendicular to V a, (this is already done, for the point b is either in $a\,c$ or in $a\,c$ prolonged,) and at the point a with the right line $a\,c$ make the angle $c\,a\,b'$ equal to the given inclination. Draw $c\,b'$ (from the middle of $a\,d$) perpendicular to $a\,c$, and draw the right line $a\,b$ perpendicular to a V. Make $a\,b$ equal to $a\,b'$. Join b V, and a V b is the angle of the oblique face required; consequently, $a\,b$ or $a\,b'$ is the length of the common rafters, and V b is the length of the hip rafters. This comprises the first example.

The second example is the same case of the right trehedral as when there are given the oblique face A V B, and the opposite face C V B of a right trehedral to find the inclination. (13.) This has already been done. The reference now given is sufficient, in order to make the demonstration understood.

† The angles which are already found will give also the bevels of the jack rafters. For the same bevel which is applied to finding the angle which the upper arris and the joint between the back of the purlin and the adjacent face of the adjacent hip rafter make with each other, will give the angle which the longest arris of the back of a jack rafter and the joint of the back of the jack rafter, and the adjacent vertical face of the adjacent hip rafter make with each other, by deducting a right angle from the angle made by the upper arris and the joint of the back of the purlin upon the hip rafter. The other bevels of the jack rafters are the same as the angle which the upper arris of one of the vertical faces of a common rafter makes with the joint between that face and the vertical face of the ridge piece.

Part 2. Draw *e f* parallel to A D, and F *f* parallel to E *e*, and join *f* D. From the point A with the radius A B describe an arc, and from the point *e* with the radius *e* A describe another arc intersecting the former arc in the point *b′*. Join A *b′* and *e b′*. Upon *e f*, as a line of symmetry, describe the figure *e f c b* symmetrical to the figure *e f* D A, and lastly, upon D *f* describe the triangle D *f c′*, so that D *c′* may be equal to D C and *f c′* equal to *f* D. Then the several faces of the covering are *e f c b*, *e f* D A, *e* A *b′*, and *f* D *c′*.[*]

Section IV.

A curved surface is that which, if cut by a plane, the section may be a curve.

A cylindrical surface is a curved surface on which only one right line can be drawn through a given point, and two right lines being drawn through two given points will be parallel.[*]

Every right line drawn on a cylindrical surface is called a *line of direction*.

If a solid having a cylindrical surface for its superficies be cut by a plane perpendicular to any line of direction, the section of the solid is called a *right section* or *profile*, and every section of the solid which is neither parallel nor perpendicular to a line of direction is called an *oblique* section; moreover, every section of the solid passing along a line of direction is called a *longitudinal* section, and every section which is not a longitudinal section is called a *transverse section*.

Hence every right as well as every oblique section is a *transverse section*.

If the transverse section of a cylindrical surface be one continued curve, the cylindrical surface is said to be *close*; but if the transverse section be open, the cylindrical surface is also said to be *open*.

If an open cylindrical surface terminate in two right lines, the two right lines are called its *rectilinear terminators*.

If the right section or profile of a cylindrical surface be the arc, or the circumference of a circle, the cylindrical surface is called a *cylindric surface*.

If the profile be the curve of an ellipse, the cylindrical surface is called a *cylindroidic surface*.

Of ceilings.

A ceiling is that apparent surface of a room which is opposite to the floor, and is of such a nature that a right line which is perpendicular to the horizon can only meet the ceiling in one point.

Cylindrical.

A simple *cylindrical* ceiling is that which consists of one cylindrical surface only.

Waggon-headed.

A *waggon-headed* ceiling is that which consists of only one cylindrical surface terminating upon the vertical faces of four walls, in such a manner that every right line which is entirely upon the cylindrical surface is comprised between the vertical faces of two opposite walls.

Hence it is evident that in a waggon-headed ceiling, that the concave surface will meet the vertical faces of the other two walls in two right lines, and that the two right lines will be parallel.

The springing lines of a waggon-headed ceiling are the two right lines in which the cylindrical surface meets the face of two opposite walls.

A plane surface comprised by the two springing lines is called the base of the cylindrical surface.

A close transverse section of a waggon-headed ceiling upon a plane comprised by the curved surface and its base, is called a transverse section of such a ceiling, and the right line which joins each extremity of the curve is called the *base of the section*.

The direction of a cylindric ceiling is the same as that of any of its lines of direction. When a ceiling is formed by two cylindrical surfaces intersecting each other so that a line of direction drawn upon either of the cylindrical surfaces through any point whatever may meet a line of direction upon the other cylindrical surface, such a ceiling is called a *return cylindrical vault*, and each cylindrical surface is called a *branch*.

If a plane be a tangent to the two cylindrical surfaces of a return vault, the two right lines in which the tangent plane touches the two curved surfaces of each cylindrical branch are called the *summit lines*, and the tangent plane is called the *plane of the summit*.

If the rectilinear terminators be both in a plane parallel to the plane of the summit, each of these terminators is called a *springing line*. A groin in a vault or ceiling is the intersection of two concave surfaces, when the angle which they make with each other projects and when the line of common section breaks the continuity of the surface upon either side of it.

Rectilinear quadrangular groin.

A ceiling is called a *rectilinear quadrangular groin* ceiling, when it is compounded only of concave cylindrical surfaces, consisting of four separate branches which have only one common point, and of which two are in one cylindrical surface, and the remaining two in another cylindrical surface, and of which the two branches contained in either of the cylindrical surfaces are entirely on the convex side of the cylindrical surface which contains the other two branches.

Hence every rectilinear quadrangular groin ceiling has four groins.

The point in which all the four branches, or in which the four groins meet, is called the *centre of the ceiling*.

If a plane touch the convex superficies of all the cylindrical parts, the plane is said to be a tangent to the surface of such a ceiling, and it will contain the centre of the ceiling.

When the profiles of all the four branches are equal curves, or such as may coincide when their summits and when each branch may be divided by a vertical plane parallel to any line of direction into two symmetrical parts, and when the cylindrical surfaces intersect each other at right angles, the ceiling is called a regular groin.[*]

---

[*] *Observation.* The first part of this process is the same case of the right trehedral as when the two right faces are given, to find the oblique face; (24.) therefore, having found the angle *g* A *e*, the angle *g* D *f* will be found in the same manner. Fig. 22 is given as an example in which both hips and valleys occur; but as hips and valleys are all described by the same case of the trehedral, a bare inspection of fig. 22 will render the construction sufficiently evident.

[*] *Illustrations of the preceding Definitions and of the Construction of the Centrings for Groin Ceilings.*

Fig. 1, pl. iv. A perspective view of a groin ceiling, supposed to be executed in masonry. This view exhibits pilasters projecting from the piers between the apertures with circular bows projecting from the cylindrical surface of the ceiling; being supported by the imposts over the pilasters.

Centrings to groin ceilings is the wooden mould upon which the masonry or brickwork is turned; therefore the reverse of the surface

Example. Given the profile W V X, pl. iv. fig. 4, of the cylindric surface of one of the transcripts, to find the profile of the nave and the coverings of the curved surface in plano.

In the curve W V X take any point M and draw M P perpendicular to the ground line fg, meeting the base W X in P. Draw P i perpendicular to W X, meeting the ground line fg in i, and draw ij perpendicular to fg meeting the projection ac of the groin above ac in j. Let wx be the base of the rib of the nave, be perpendicular to the projection of the axis of the cylindrical surface, and draw jp perpendicular to wx meeting wx in p. Draw pm also perpendicular to wx, and make pm equal to P M. Then m and M are corresponding points, and thus to the axis wx the point m is a point in the curve.

In this manner, having found a sufficient number of points, the curve may be drawn through these points, which, being done, is the right section of the nave part of the groin ceiling.

To find in plano the curved surfaces of the two transepts. Let $\gamma\delta$ be the projection of the right section of a profile of the cylindric surface of one of the transepts, and $\alpha\beta$ that of the nave. In the given curve W V X take any point M and draw the line as before, and let ij intersect $\gamma\delta$ in l, also let jp intersect $\alpha\beta$ in k. Extend the curve W V X into the right line qr, No. 3, and in qr, No. 3, let ql and rl be each equal to the arc W M, No. 2. Draw tj, No. 3, perpendicular to qr, and make lj equal to lj, No. 1; and in this manner a sufficient number of points may be found to construct the whole figure $qsutr$, which will be the form of the boarding of one of the transepts in plano.

In like manner $sqrlu$, the boarding of the nave in plano, may be found.

Fig. 5 exhibits the plan and elevation of a groined ceiling to be formed with lath and plaster, the construction of the ribs is found in the same manner as in fig. 4; but here, as well as the right ribs, we shall also require to find the groin ribs. The method for this purpose will be sufficiently evident by merely inspecting the plan in which it is traced upon the diagonal bd, the ordinates being of the same height as in the two profiles. Thus let the semicircle abc be the stretch-out of the groin ceiling, exhibited in the elevation, No. 2, fig. 5. In the semicircular arc abc, pl. v. fig. 1, take a sufficient number of points; but for the purpose it will be sufficient to take these points in the quadrant or half arc; and through these points draw ordinates, and draw gi and df in any convenient situation. Make df and gi respectively equal to bd or ac, pl. iv. fig. 5, No. 1. Then in pl. v. fig. 1, let bj be one of the ordinates of the semicircle meeting the base ac in j, and divide df and gi in p and q, in the same proportion as ac is divided in j. Draw pe and qh respectively perpendicular to df and gi. Make pe and qh each equal to the ordinate jb of the semicircle, and thus the points e and h are in the curves of which the bases are df and gi. The curve being drawn through a sufficient number of points thus found, the curve of the angle rib will be def, and the curve of the ribs of the nave will be ghi. But if the curve of the half of each rib be found, the other being symmetrical will be found in the usual manner. Thus drawing the line cn, take the half of df and the half of gi, and with these distances from the centre o of the semicircle cut the right line cn in n and m. Join rn, rm, and draw lines parallel to cn, which will divide the half bases of the ribs as required.

Example. Given the plans A b N P, O N P Q, pl. iv. fig. 6, of two inclined vaulted passages meeting each other at an angle in a vertical plane; the angles which the springing lines of the arches make with the level plane and a vertical section of the first vault intersecting the springing plane in a line perpendicular to the two springing lines; it is required to construct these vaults with plaster, and to place all the ribs in vertical planes, so that the bases of the common ribs may be perpendicular to the springing lines: the things required to be done by a geometrical construction is to trace the curves on both sides of each half of the angle rib, so that the edge may range in both directions of the vault, as also to trace the curves on each of the faces of the common so as to range in their respective directions,

Let A b and b N, fig. 6, be reciprocally perpendicular to each other. Make the angle N ba equal to the angle of inclination of the springing line of the first direction of the passage, and draw N a perpendicular to b N. Prolong O N to S, and draw N R perpendicular to O S. Make N R equal to N a and make the angle N R S equal to the complement of the angle which the springing line of the second direction of the vault makes with the plan. Prolong T R to meet O N in S, and prolong b A and N P to meet each other in m. Draw N U perpendicular to N P. Make N U equal to N R or N a, and join m U and m S.

We have now given the two right faces, N m S and N m U, of a right trehedral; therefore (17.) (20.) find the inclination mqk, which is the angle made by the plane of the angle rib, and the springing plane of the upper direction of the vault. Draw B C perpendicular to b N.

Let A bnp and $qpno$ (fig. 7) be the springing planes of each direction of the vault, the angles pnb and pno being respectively equal to pnb and $p'n'o'$, (fig. 3,) and b A (fig. 4) equal to b A (fig. 6.) Let b A (fig. 7)

---

of the groined ceiling which is concave. In practice, the centres are placed first over the widest avenue (or nave) upon a horizontal timber bar at each of the springing lines of the cylindric surface, the two springing lines being upon the level. The two horizontal timber bars are supported by posts, distributed at regular intervals without any regard to the transverse vault, and the centres are placed over the posts, and boarded in without being interrupted by the transepts. Then the groins or intersections of the two cylindric surfaces are drawn upon the boarding over the nave; and the uprights, the beams in the springing, the centres, and the boarding, are all placed on the concave side of the centring of the nave. Fig. 2 is a perspective representation of the centring of a groin vault. This view exhibits the nave completely boarded in, with the centres and their necessary supports in the transepts. Fig. 3 exhibits another perspective view which shows both parts boarded in and ready to be built upon.

Fig. 4 is the plan and elevation of a groin ceiling; No. 1 being the plane, and No. 2 the elevation of the transepts. Here the groins are formed by the intersections of a cylindric arch upon the planes of the diagonals. The elevation is here taken upon a plane perpendicular to the axis of the cylinder, fg being the ground line.

The sides of the plan are perpendicular to each other, and the plan and elevation are so placed in respect of each other that right lines drawn from any two corresponding points perpendicular to the ground line will meet the ground line in the same point; and thus all right lines parallel to the axis will be projected in the plan into right lines perpendicular to the ground line, and in the elevation these right lines will be projected into points. It is unnecessary to say more with respect to the orthographical drawings, since those who are familiar with plans and elevations will find the reason and meaning of every line in the construction by merely inspecting the drawings. In the plan, ac and bd are the projections of the groins.

be perpendicular to $n b$, and let b A be prolonged from each extremity towards $e e$. Through any point e in $e e$ draw $e d$ perpendicular to $e e$, and make the angle $d e f$, No. 1, equal to the angle $a b c$. (Fig. 6.) Let the seat $p n$ (fig. 7) of the angle rib be prolonged from each of its extremities to $e' e'$. Find (26.) the inclination of a plane which shall have a given trace $e'' e'$, and which shall be parallel to the right line of which the seat is $e d$, No. 1, and the angle of projection $g e f$.

Let $d' e' f'$, No. 2, be the angle thus found. From the point e', No. 3, draw $e'' d''$ perpendicular to $e'' e'$, and make the angle $d'' e'' f''$ equal to the angle $m l k$, fig. 6.

Again, find the inclination of a plane which shall have a given trace $e''' e'''$, and which shall be parallel to a right line, of which $d e$ is the seat, and $d'' e'' f''$ the angle of projection, and let $d''' e''' f'''$ be the angle thus found.

From any point g' in $e' d'$, No. 2, draw $g' h'$ parallel to $d e$, No. 1; draw $g f$ perpendicular to $e' d'$ and prolong $d' e'$ to i'. Make $e' i'$ equal to $e' f'$, and join $h' i'$. Let the given curve of the rib be A D b. From any point C in the base A b of the given curve of the rib draw C D perpendicular to A b, and draw C E parallel to $b n$, meeting $p n$ in E. Draw E F parallel to $h i$, No. 2, and make E F equal to C D, and F is a point in the curve. In the same manner as many points F, F may be found as will be sufficient to trace the curve. These points being actually found, draw the curve p F n from the one extremity p through the points thus found to the other extremity n.

The curve p Q n is identical to the curve p F n, therefore the ordinates E Q make the same angle with $n p$ as the ordinates E F make with $n p$; hence all the ordinates E Q are respectively equal to the ordinates E F.

To prevent confusion in describing the ranging curves for the two faces of each half rib, the reader's attention is directed to a separate diagram, No. 5. In No. 5, draw $p n$ parallel to $p n$, fig. 7, and equal to it, and draw $n b$ and p A, No. 5, parallel to $n b$ or p A, fig. 7. Then, in No. 5, prolong $p n$ to any convenient point e, and draw $e d$ perpendicular to $e p$. Make the angle $d e f$ equal to the angle $m l k$, fig. 6. Again, in No. 5, draw $h m$ parallel to $e f$, and at such a distance from $e f$ as will be equal to the thickness of the half angle rib.

Let $m k$, No. 5, meet $d e$ in k. In $e f$ cut off the part $e l$ equal to $e k$, and draw $l u$ parallel to $b n$ or A p. Draw $l v$ and $k u$ parallel to $n p$, and draw $u v$ perpendicular to $l v$, and join $t v$. Let the curve n F p be identical to the curve n F p, fig. 7, and let F, F, F, &c., No. 5, be any number of points in the curve n F. Draw $n r$ and $p q$ parallel to $l v$ to meet $t u$, or $t u$ prolonged in q and r, and draw the right lines F G, F G, F G, &c. parallel to $t v$. Make F G, F G, F G, each equal to $t v$.

A sufficient number of points, F, F, F, &c., being thus found, draw the curve r G q, then r G q will be the higher curve of the intrados of the lower half rib.

The curves n Q p, n F p, fig. 7, being the mitre curves, must necessarily be identical in order to coincide; hence the ranging curve of the upper angle rib will be found in the same manner from the mitre curve, as the mitre curve was found from the ranging curve of the lower half-angle rib; but to remove all doubts from the mind of the reader, we shall also show the manner in which this is to be done.

Draw $k'' m''$, No. 3, parallel to and at such a distance from $e'' f''$ as will be equal to the thickness of the half rib, and let $m'' k''$ meet $e'' d''$ in k''. From any convenient point w in $p n$ draw $w u$ parallel to $n o$ or $p q$, and draw $l'' v$ and $k'' u$ parallel to $p n$. Draw $u v$ perpendicular to $p n$, and join $v w$. Let Q Q Q be any number of points in the curve n Q p. Draw Q R, Q R, Q R, &c., parallel to $w v$, and make Q R, Q R, Q R, &c. each equal to $a v$, then r R t is the ranging curve of the upper half rib required.

In order to find the curve of the face and the ranging curves of the ribs in the ascending direction of the vault. It will be necessary to find the projection of one of the ordinates, as X F, upon the springing plane $q p n o$, for this purpose, the trace $e'' e'$ of the plane of the mitre is given, as also the angle $d'' e'' f''$ of projection; this being found, X Z is the projection required; and $g'' f''$ is the projectant of the projection Z of the point F. Through any convenient point, o in $n o$, draw $e''' e'''$ perpendicular to $n o$, and through any convenient point h''' in $e''' e'''$, No. 4, draw $h''' g'''$ parallel to X Z. Make $h''' g'''$ equal to X Z, and through g''' draw $i''' e'''$ perpendicular to $e''' e'''$, meeting $e''' e'''$ in the point e'''. Draw $g''' f'''$ perpendicular to $e''' g'''$, and make $g''' f'''$ equal to $g'' f''$, No. 3. In $e''' f'''$ make $e''' i'''$ equal to $e''' f'''$, and join $h''' i'''$. Then, to trace the common rib, draw E S, No. 4, parallel to $n o$, meeting $e''' e'''$ in S, and draw S V parallel to $h''' i'''$. Make S U, fig. 7, equal to any one of the other ordinates, as E F and U thus found is a point in the curve.

In the same manner, having found as many points U, U, U, as may be necessary, draw the curve q U o, fig. 7, which, when done, is the ranging curve of the lower face. Make $e''' l'''$ equal to $e''' k'''$, and draw $l''' j'''$ perpendicular to $e''' i'''$, meeting $e''' i'''$ in j'''. Draw the ranging lines U V, U V, U V, &c., of the edge of the rib, and make U V, U V, U V, &c., each equal to $k''' e'''$, No. 4. Draw the curve x V y, and it will be the ranging curve required.

Fig. 8 exhibits the same plan when the springing planes of the two directions are level; hence in this case all the difficulties of the former disappear since the planes of the faces of all the ribs will be perpendicular to the springing plane, and all the ordinates of the curves perpendicular to their springing lines or bases; moreover, the heights of these ordinates which are in vertical planes, parallel to the axis, will be equal, and the ranging lines of the edges of the ribs will be parallel to the bases of the curves. The whole is so evident from the figure as to render any further explanation unnecessary.

SECTION V.

One surface is said to fit another, when every point of the first surface coincides with a point in the second.

Cove.

Any concave surface whatever in a ceiling is called a *cove*.

When a cove is intended to be formed in a ceiling with plaster upon lath, a receding surface, everywhere equally distant from the apparent surface of the cove to be formed, sufficient to contain the thickness of the lath and plaster together, is called the lathing surface of the cove.

It is evident that if the apparent surface to be formed be a cylindric surface, the lathing surface will also be a cylindric surface; and if the apparent surface to be formed be a spherical surface, the lathing surface will also be a spherical surface: but this will not hold universally.

If a part of a piece of wood be taken away, so that the new surface formed by the part taken away may fit the lathing surface of a cove continued from one extre-

Rib or Bracket.

mity of the surface to meet the other, such a piece of wood is called a *rib* or *bracket;* and the surface thus fitted is called the *ranging edge* of the rib or bracket. Hence a continued line may be traced on the ranging edge of the bracket from one extremity of the cylindric surface to the other.

If two cylindric surfaces intersecting each other be the lathing surface of two coves, and if the entire intersection coincide in every point with the surface of a piece of wood, and if a portion on each side of this intersection of the superficies of the wood fit each of the lathing surfaces close to the intersection, such a piece of wood is called an *angle rib* or *angle bracket;* and the parts which fit upon the cylindrical surfaces are called the *ranging parts of the surfaces of the angle rib,* or *angle bracket.* A rib or bracket thus fixed is said to be *properly placed.*

In order to form any surface whatever with plaster upon lath, it is evident that every lath must at least be supported in two points; and that the thinner the lath is, the number of points in which it is supported must be more in order to be sufficiently strong to carry the plaster upon which the apparent surface is to be formed.

Hence in forming a coved surface with plaster upon lath, ribs or brackets receding from the lathing surface are generally fixed at such distances from each other, that every lath may be supported upon the ranging edges of the ribs or brackets at three or more points in its length, and that the ribs or brackets thus fixed may have their ranging edges in the lathing surface. When the apparent surfaces of the plaster are required to be formed by two cylindric surfaces intersecting each other, the lathing superficies will also be two cylindrical surfaces intersecting each other. In this case it will be found convenient to fix one extremity of the lath to an angle bracket, and the laths throughout upon a sufficient number of ribs or brackets properly placed. All ribs or brackets, except angle ribs or angle brackets, are called common ribs or common brackets.

In the construction of cylindrical coves in the ceiling of a room to be formed with plaster upon lath, the lath is generally supported upon brackets, and the cylindric surfaces meet each other in such a manner that one of them may terminate upon every vertical plane face of the room, and upon a plane forming the apparent intermediate surface of the ceiling; and that all the terminations of the cylindrical surfaces upon the walls may be in a plane parallel to the plane of the intermediate surface of the ceiling, and that every termination in the ceiling may be parallel to the vertical adjacent surface of the room: such a ceiling constructed with plane and cylindrical surfaces is called a cylindrical, straight, coved, and flat ceiling, or, more generally, such a ceiling is called simply a *coved ceiling.* Hence the plastering of the cove of every straight coved and flat ceiling will require as many angle brackets as the room has plane vertical faces.

In order to save timber, every rib or bracket in the construction of a cylindric surface ought to have two surfaces in parallel planes, which may always be perpendicular to every line of direction of the lathing cylindrical surface. These parallel plane surfaces are called the planes of the brackets. Hence when a cylindrical cove to be formed with plaster upon lath is required to be constructed, and to have any line of direction parallel to the horizon, if the brackets are fixed so that their surfaces may be perpendicular to the horizon, the ranging edges of the brackets will be perpendicular to the planes of these brackets; but, whatever be the position of a line of direction, the planes of every two brackets which range in a cylindrical surface are generally perpendicular to the horizon, and parallel to the plane vertical surface of the wall; and thus, when a line of direction of the cylindrical surface in which the ranging edges of the brackets are placed is not parallel to the horizon, this line of direction will not be perpendicular to the planes of the brackets.

Brackets to form small cylindrical coves with plaster, seldom require more timber than can be obtained from a board in one single piece; but ribs to support lath and plaster, as well as the brackets of large cylindrical coves, require that each rib or bracket may be formed in two or more pieces of boards joined together, so as to form a whole bracket in two thicknesses; and that the joint between the two halves may be in a plane parallel to the planes of the rib, and equidistant from these planes. When two cylindrical surfaces intersect and form a plane curve, it will be convenient to make the angle rib or angle bracket, if large, in two thicknesses, so that the joint between them may be in a plane parallel to the planes of the angle rib or angle bracket.

The cylindrical surfaces which are generally used in coved ceilings, intersect each other in a plane curve, and the plane of this curve is generally perpendicular to the horizon. Moreover, two right sections of the two cylindrical surfaces are generally such that the two curves will reciprocally coincide in all parts. In this general case it will be found convenient to form angle ribs or brackets in two thicknesses of boards, and the joint or plane of coincidence to be in a plane of the curve in which the two cylindrical surfaces meet each other. It is evident that all the parallel plane surfaces which comprise the brackets are sections of the cylindrical surface in which they may be arranged, and when two faces of every two brackets are parallel to one another, as in common brackets, and their ranging edges in the same cylindrical surface, that the sections of these brackets, by the cylindrical surface, are identical curves; and that the curve lines of all the parallel ribs or brackets are identical curves. Moreover, as cylindrical surfaces are generally so situated in coved ceilings that their lines of direction are parallel to the horizon; and as all the ribs or brackets are generally, and most conveniently arranged in parallel planes, these planes will be all perpendicular to the lines of direction of the cylindrical surface into which their edges are arranged; hence all the ranging edges of these brackets will be perpendicular to their vertical faces; so that, if a right section of the cylindrical surface is obtained, and a mould be made so as to contain this section, this mould will serve to draw the curves on one of the faces of every common bracket; and these being properly fixed with angle brackets when necessary, will be in the lathing surface required.[*]

---

[*] The cylindrical surfaces commonly employed are those of cylinders, or those which have their right sections greater or less portions of the circumference of a circle. Sometimes, however, various other curved surfaces may be used with good effect. Of these the cylindrical surfaces generally employed are those of cylindroids; and the curves of the right sections of cylindroidal surfaces are, generally, either quadrantal portions between the two axes, of which one is horizontal and the other vertical.

Every cylindrical surface used in coving will be sufficiently determined by having given a right section of the cylindrical surface. Moreover, two cylindrical surfaces intersecting each other will be

To find the ranging edge, we have only to cut through the thickness of every such board perpendicular to the two plane faces by taking away the part on the concave side of every rib or bracket, in order to form the ranging edges required.

Examples to the preceding Observations in ranging the Ribs of Groin and Cove Ceilings.

Example 1. Let pl. v. fig. 2 be the plan of a portion of a coved surface at an internal angle, *a e* and *a m* the springing lines, *b n* and *b f* the ceiling line in each return. The angle bracket is traced in the same manner as the angle rib of a groin: *a b d c* is the plan of half the angle rib, *a b* the base of the mitre curve, and *b h* perpendicular to *a b* the height, the curve itself being *a h*.

Draw the chord *a h* of the curve, and draw *c k* perpendicular to *a b*, meeting *a b* in *k*, and draw *k l* perpendicular to *a h*, meeting *a h* in *l*.

Let *a e f b*, No. 1, be the edge of a board, out of which a bracket is to be formed, *a b c d* and *e f g h* the two faces of the board which comprise the edge *a e f b* between them. Draw the right line *o q* perpendicular to *a b* or *e f*, intersecting *a b* in *p*, and *e f* in *q*, and make *p o* equal to *l k*, fig 2. In No. 1 and in No. 2 through *o* draw *i n* parallel to *a b*, and in *i n* make *o n* equal to *a l*, fig. 2. Apply the mould *a h*, fig. 2, to No. 1 and No. 2, so that the extreme points *a* and *h* of the curve, fig. 2, may be in the arris line, *e f*, No. 1 and No. 2, *viz.* the point *a*, fig. 2, upon the point *q*, No. 1 and No. 2, and the point *h*, fig. 2, upon the point *l*, No. 1. Then, upon the face *e f g h* draw the curve *q r l*. Remove the mould from the face *e f g h*, and place it upon the other face, *a b c d*, so that the points upon *q* and *l* may be in *n i*; *viz.* *q* upon *n*, and *l* upon *m*. Then, upon the face *a b c d* draw the curve *n s m*. The two curves *n s m* and *q r l* are the curves in the parallel faces of the brackets; then the wood on the concave side being cut away will give the ranging required. No. 1 and No. 2 being put together as they ought to be, will complete the angle bracket for its situation.

Example 2. Let pl. v. fig. 3 be the plan of a portion of the curved surface at the external angle, *o y* and *o t* the springing lines, *p s* and *p z* the ceiling lines in each return. The angle bracket being traced as before, *o p r q* is half the plan of the angle rib, *o p* the base of the mitre curve, and *p x* perpendicular to *o p* the height, the curve itself being *o x*.

Draw the chord *o x* of the curve, and draw *q u*, meeting *p o* prolonged in *u*. Draw *u v* parallel to *o x*, and draw *o w* perpendicular to *u v*, meeting *u v* in *w*. Let *a e f b*, No. 3 and No. 4, be the edge of a board, out of which a bracket is to be formed; and let *a b c d*, *e f g h*, be the two faces of the board which comprise the edge *a e f b* between them. Draw the right line *i l* perpendicular to *a b* or *e f*, intersecting *a b* in *l*, and *e f* in *k*; and make *k i* equal to *o w*, fig. 3. In No. 3 and No. 4 draw *i v* parallel to *a b*, and in *i n* make *i m* equal to *o u*, fig. 3.

Apply the mould *o x*, fig. 3, to No. 3 and No. 4, so that the extreme points *o* and *x* of the curve, fig. 3, may be in the arris line *a b*, No. 3 and No. 4; *viz.* the point *o*, fig. 3, upon the point *q*, No. 3 and No. 4; and the point *x*, fig. 3, upon *l* in No. 3 and No. 4. Then upon the face *a b c d*, in No. 3 and in No. 1, draw the curve *l r q*. Remove the mould from the face *a b c d*, and place it upon the other face *e f g h*, so that the point upon *q* and *l* may be in *ni*; *viz.* the point *q* upon *n*, and *l* upon *m*; then upon the face *e f g h* draw the curve *m s n*. The two curves *n s m* and *q r l* are the curves in the parallel faces of the bracket. Then the wood on the concave side being cut away so as to form the cylindrical surface, will give the ranging required.

Example 3. Fig. 4 is the plan of an equilateral and equiangular cylindric groin ceiling, the ribs across the diagonals are in half ribs, and every half rib is the same as an angle bracket upon an external angle. In this Example the arches are semicircular, and of the same radius as the quadrantal circular arcs, fig. 2 and 3, of the common brackets, and therefore the mould for each half angle rib of the groin ceiling is the same as is found for the angle ribs, Examples 1 and 2; and, as the angles of the groin are all external, the ranging of each of the ribs will be found in the same manner as the angle bracket, fig. 3; and this will be evident by again reading the description to the second Example to the groin ceiling, fig. 4, where the same letters of reference are applied as in fig. 3.

Example 4. Fig. 5 exhibits the plan of an oblong cylindric groin; No. 9 exhibits the face mould; No. 6 and No. 7 the application of the face mould to the ranging of one of the half ribs; No. 8 and No. 9 the application of the face mould to another of the half ribs which form an acute angle with the former.

Fig. 6 exhibits an application of the same principles to the backing of common or hip rafters.

SECTION VI.

Cylindro cylindric ceilings.

A proper *cylindro cylindric ceiling* is a ceiling, or part of a ceiling, formed by two cylindric surfaces intersecting each other in such a manner that they may have four branches; and that no part of either of the cylindric surfaces may be comprised within the concave surface of the other; and that all the springing lines of the two cylindric surfaces and the axis may be in one horizontal plane, and that the two cylindric surfaces may not have a common tangent plane.

A proper cylindro cylindric ceiling is given when the plan of the springing lines are given in a plane parallel to the plane which contains them; and when the right sections of the portions of the cylindric surfaces terminated by the springing lines are given.

Example. Let *a l* and *s v*, pl. v. fig. 7, be the two springing lines for one of the cylindric surfaces, and *c u*, *c t*, the two springing lines for the other cylindric surface; and let *c d e* be the section of the cylindric surface, of which the springing lines are *e u* and *c t*; and let *a q s* be the section of the cylindric surface, of which the springing lines are *c l* and *s v*; and let *e c* be the base of the curve *c d e*, and *a s* the base of the curve *a q s*. Moreover, let *a l* intersect *c t*, and *c u* in *b* and *f*; then *b* and *f* are the plans of the springing points of the

---

given when the right sections of these are given, and when the angle which two lines of direction make with each other are given; but these will not be sufficient to fix ribs or brackets in their situations with regard to the vertical faces of the rooms and the plane in the intermediate part of the ceiling. In this case we must have given, besides a right section of the cylindrical surface, a plan and elevation of the springing and ceiling lines of each of the two cylindrical surfaces.

The same principles extend to the construction of lathing surfaces, whether they may be coves in ceilings or otherwise.

intersection upon one side. It is now required to find the projection of the two cylindric surfaces.

In the curve *c d e* take any point *d*, and draw *d m* perpendicular to *c e*, meeting *c e* in *m*. Draw *m n* parallel to *c t* or *e u*; and from the point *o* in *a s* draw *o p* perpendicular to *a s*. Make *o p* equal to *m d*, and draw *p q* parallel to *a s*, meeting the arc *a q s* in *q*. Draw *q r* perpendicular to *a s* meeting *a s* in *r*, and draw *r n* parallel to *a l* or *s r*. Then the point *n* is the projection of an intermediate point in the curve of which *b* and *f* are the projections of the springing points. In this manner may be found as many points as will be necessary to trace the curve *b x f*, which is the plan of the intersection required; and in this manner the plan *t y u* of the opposite intersection will be found.

The plans of the two intersections are thus found by projection; but, as it is known that the projection of two cylindric surfaces are hyperbolas when the right sections of both cylindrical surfaces are circular arcs of different radii, and when the projection is made upon a plane which contains the two axes of the cylindrical surfaces, the intersections may therefore be found independent of the principles of projection. We shall here show by an example how this is to be done.

Let the semicircles *a b c*, *d e f*, fig. 8 and 9, be the right sections of the cylindric surfaces, *a c* and *d f* being the diameters of these semicircles placed upon the same right lines having the same centre, and let *g i* and *h j* be the springing lines of the cylindric surface which has the greatest diameter, and let the springing lines be parallel to *d f*.

Draw *e m* and *a n* perpendicular to *g i* or *h j*, intersecting *g i* in *k* and *l*, and *h j* in *m* and *n*; and draw *b e* parallel to *a c*, and a tangent to the semicircle *a b c*, to meet the semicircle *d e f* in *e*. Draw *e u* perpendicular to *d f*, meeting *d f* in *u*, and bisect *k l* in *s*. Draw *s t* perpendicular to *k l* intersecting *m n* in *t*, and in *s t* make *s o* and *t p* each equal to *f u*; then, having the vertices *o* and *p* of the two opposite curves of an hyperbola, describe the curves *k o l* and *m p n*; and these will be the projections of the two intersections required.

Fig. 8 is adapted to the same plan as fig. 7. In fig. 9 the two cylindric surfaces are nearly equal; that is, their diameters are nearly equal to one another. The manner of drawing the two hyperbolic opposite curves as shown by dividing each ordinate into the same number of equal parts, and dividing the ends of the rectangle into the same number of equal parts; then, drawing right lines from the opposite vertices to these points, to intersect as in the figures.*

Example. Given the projections of the springing lines, the heights of the cylindrical surfaces, and the height of the spheroidal surface above the springing plane, which is parallel to the plane of projection, to find the projections of the intersections of the curved surfaces.

Let fig. 10, No. 2, be the elevation, and let No. 1 be the plan. In No. 1 let A P E Q be the springing line of the spheroid, and let *t u* and *t′ u′* be the springing lines of one of the cylindric surfaces, *x y*, *x′ y′* the springing lines of the opposite cylindric surfaces; also let *v w*, *v′ w′* be the springing lines of the passages in the transverse direction; and let *r s*, *r′ s′* be the springing lines of the opposite end of the transverse direction. In the construction of the hyperbolas, which are the projections of the intersections of the curved surfaces of the cylindric surfaces, are given the double ordinates K K′, I I′, L L′, and N N′, and the axis B D and X Z, to describe the hyperbolas, which being done, let the curves be K′ B K, G H I, L′ D L, and Y Z M, which will be the projections of the intersections of the curved surfaces required in the horizontal plane.

The parts *u* K N′ *v′*, *r* N L *x*, *x′* L′ I′ *r*, and *r′* I K′ *u* of the plan are pilasters placed under the springings between the intersections of the curved surfaces.

In the elevation No. 2, let *β γ* be the ground line, and let it be perpendicular to P Q, and hence parallel to A E, then the right sections of all the cylindric surfaces being semicircles, the cylindric surfaces of which their axes are perpendicular to the elevation will be projected into semicircles, of which their diameter will be parallel to the ground line. Let this projection be made, and let it be *g h i*, No. 2, and let *f h* be the radius perpendicular to the terminating diameter *g i*. Prolong *g i* to *a* and *e*, and make *f e* and *f a* each equal to C A or C E, No. 1, the radius of the circle of the spheroid contained in the springing plane. Through *h* draw *n p*, No. 2, parallel to *a e*, and draw B *b*, D *d* perpendicular to the ground line *β γ* to meet *n p*, No. 2, in *b* and *d*. Draw C *c* perpendicular to the ground line *β γ*, and from either of these points *b* or *d*, as *d* with a radius equal to *f a* or *f e*, cut C *c* in *g*. Draw *g d* intersecting *a e* in *r*, and make *f c* equal to *r d*. Then by means of the axis major *a e*, and the semiaxis minor *f c*, describe the semi-ellipse *a b c d e*, and *a b c d e* is the section of the spheroid required; from this the ribs of the ceiling may be constructed. The lines *k b* and *l d* are the projections of the two intersections of the curved surfaces, of which their projections are the hyperbolic curves K′ B K, L′ D L.

SECTION VII.

A *pendentive* ceiling is a ceiling consisting of the portion of a spherical or of a spheroidal surface, comprised by the vertical faces of the walls of a room.

Pendentive ceilings.

A proper *spherical* or *spheroidal*, *pendentive* ceiling is a ceiling comprised by the vertical faces of the four walls of a room rising from a rectangular plan, so that the intersection of the vertical diagonal planes of the room may pass through the centre of the spherical or spheroidal surface.

A *regular, polygonal, spheroidal, pendentive* ceiling is a spheroidal surface comprised by the vertical planes containing the inner faces of three or more adjacent walls, rising from a plane which is a regular polygon in such a manner that the axis of rotation of the spheroidal surface, being prolonged, may pass through the centre of the polygonal plan.

A *proper, quadrangular, spheroidal, pendentive* ceiling is the portion of a spheroidal surface comprised by the vertical planes which contain the four inner faces of a room, of which the plan is a rectangle, and of which the vertical, diagonal planes intersect each other in a right line containing the axis of rotation of the spheroidal surface.

---

* If two equal semicylindric surfaces intersect a spheroidal surface, so that the axis of the semicylindric surfaces may intersect each other at right angles in the centre of the spheroidal surface: and that the springing lines of the two cylindric surfaces, and the springing line of the spheroidal surface, and the two axes of the cylindrical surfaces may be all in the same plane; and that the springing line of the spheroidal surface may be the circumference of a circle, of which the diameter is greater than that of either of the cylindrical surfaces, and that no part of any of the cylindrical surfaces may be within the concave side of the spheroidal surface; such a ceiling is called a proper *spheroido cylindric ceiling*.

The projections of the four curves upon the springing plane, of the four intersections of the cylindric surfaces, and the spheroidal surface, are hyperbolas, having their axes terminated by the vertices of the curves in each pair of opposite projections.

pringing urve.

The intersection of a spherical or spheroidal surface and the plane of every wall of the room, is called a *springing curve*.*

In the construction of pendentive ceilings it will be convenient to place all the ribs in vertical planes passing through the centre of the sphere or spheroid; for in this position of fixing the ribs all the ribs may be formed by means of one mould only; since in this position they will all have the same curvature and will all intersect in one point of the spheric surface. In order to divide the ribs equally, it will also be convenient that the vertical planes which contain the curves of the ribs may make equal angles with one another, and that four of these ribs may be in the two diagonal planes. We shall call the ribs placed in these planes the diagonal ribs; hence if one of the diagonal ribs be found, every radial rib will be less than a diagonal rib.

Example. Let it be required to construct a spherical pendentive ceiling over a given square plan A B C D, pl. vi. fig. 2.

Then, because the chords of the springing curves are equal to the sides of the plan, and since in this example the sides of the plan are all equal, the chords of the springing curves to any side of the plan are equal.

Draw the diagonal A C, then A C will be equal to the chord of the diagonal ribs. Upon A C as a chord describe the arc A *e f* C of a circle, and the perpendicular *g h* from the middle of the chord is equal to the perpendicular from the middle of the chord of each of the springing curves. Therefore bisect the chord C D of the springing curve upon C D, and draw *i l* perpendicular to C D. Make *i l* equal to *g h*; and from the point *l*, with a radius equal to *l* D or *l* C, describe the arc C *k* D, which will not only be the springing curve for the face of the room of which the plan is C D, but also for every other face.

Now since all the radial ribs are of the same curvature and their lengths only differ, and since the curve of a diagonal rib is given, we have only to cut an arc from the curve of the diagonal so as to stand over the plan required. Thus let *r* be the middle of the curve A *e f* C, and let *m n* be the plan of one of the ribs; also let *g m* be the radius of the horizontal circle upon which this rib is intended to terminate upon. With the radius *g m* describe the semicircle *d m t*, meeting A C in *d* and *t*, and draw *d e* and *t f* each perpendicular to A C, meeting the curve A *e f* C in *e* and *f*; then A *e* or C *f* are the portions of the curve for each diagonal rib, in order either to be terminated by a horizontal cornice or by a conic skylight in the middle of the ceiling. Again from the centre *g* with the distance *g n*, the length of the plan of a rib, describe the arc *n p*, meeting the diagonal A C in *p*, and draw *p q* perpendicular to A C, meeting the curve A *e f* C in *q*; then *q e* is the portion of the curve of the edge of the rib which will stand over *m n* in the plan.

SECTION VIII.

Niche.

A *niche* is a recess in a wall generally formed by a cylindric surface standing upon a level surface and surmounted by a spheric surface, so that the axis of the cylindric surface may be vertical and may pass through the centre of the spheric surface, and that cylindric and spherical surfaces may meet each other in a horizontal plane, and that the cylindric and spherical surfaces may have the same tangent plane, and that the cylindric and spherical surfaces may be terminated each by the vertical surface of the wall.*

Example. In fig. 3, let *m*, No. 1, be the projection of the line in which the vertical planes of the ribs which pass through the centre intersect *a m*, the plan of the wall, *a d g m* the projection of the springing horizontal arc. Let this plan be divided into ribs, and let the two faces of one of these ribs be represented by the right lines *e n* and *f p*. Let the outer circle, in which the back of these ribs may be supposed to be placed, be *l p i*. From the points *e* and *f*, in which *e n* and *f h* meet the inside of the front rib, draw *e i* and *f h* perpendicular to *e n*, and let these lines meet the inner curve in *g* and *b*; then *g b i h* shows the joint at the top; *g h* and *b i* being the right lines in which this joint terminates upon each face of the rib. Of this rib *d b* is the length of the curve on the inside over *e d*, and *d g* is the length of the curve over *f o*. In this construction, as the bisecting planes of the ribs all meet in a vertical axis, the projection of this axis is the point *f*, which is the centre of the projections of all the ribs. The construction of the remaining rib will be found in the same manner as the rib now described. No. 2 is the elevation to the plan No. 1.

Again, because the top or head of the niche is a portion of a hemisphere of which the springing plane is the base, all sections of the hemisphere perpendicular to this base will be semicircles; or because the springing plane passes through the centre of the sphere, all the sections of the spherical surface perpendicular to the springing plane will be semicircles; hence the front rib of the niche will be a semicircle for the plane if the wall is perpendicular to the springing plane.

---

* The extremities of all the springing curves are in a plane parallel to the horizon, and when the surface of the ceiling is spherical, and when the plane containing the extremities of the springing curves passes through the centre of the sphere, the springing curves will be all semicircles.

If the plane containing the extremities of the springing curves be above the centre of the sphere, then the centres of the springing curves will be at the same distance below their chords, as the centre of the spheric surface is below the horizontal plane which contains the extremities of the springing curves.

Moreover, when the surface of a ceiling is spheroidal, and when the horizontal plane containing the extremities of the springing curves passes through the centre of the spheroid, and when the axis of rotation is in a vertical position, the springing curves in the planes which contain the inner faces of the walls of the room are all similar to the curve of the vertical section of the spheroidal surface passing through the centre.

A room having a regular or proper pendentive ceiling will admit of the most elegant decorations of pilasters and columns, as appears from the perspective view, pl. vi. fig. 1, where A is one of the four spherical pendentives which is formed by a horizontal cornice at the top, and the two architraves bordering upon the springing curves in the planes of two adjacent walls.

* In the construction of the head of a spherical niche, since the lathing surface of a spherical niche is spherical, as well as the apparent surface of the head, the curves of the ribs will be portions of the circumference of a circle; and if the curves of the ribs be in planes passing through the centre of the sphere, all the edges of the ribs which are in these planes will have equal curvatures, and, consequently, will have equal radii; moreover, if the ribs be in vertical planes which pass through the centre of the sphere, the planes of all the ribs will be perpendicular to the horizontal plane in which the cylindric and spherical surfaces terminate. If the surface of the wall be a plane surface, and if it contain the axis of the cylindric surface, the curves of all the ribs will be quadrants of circles which will all have the same radius; but if the axis of the cylindric surface be without the face of the wall, the curves of the ribs will be arcs of circles of the same radii, and these curves will be each less than a quadrant.

In the plan, the springing between the cylindric and spheric surfaces will be projected into the arc of a circle, and all the ribs which are in vertical planes will be projected into right lines, and the vertical line in which the back ribs intersect will be projected into a point which will be a common termination for all the back ribs.

JOINERY.

Joinery is the art of fixing various pieces of wood together, chiefly for such parts of the interior of a building as are exposed to the eye, and which are employed in the construction of doors and windows, and for forming the various margins round plaster in order to cover all external angles, and thereby protect it in its weakest parts from injury or accidental violence, so as to render these parts comfortable, convenient, and agreeable to the eye.

Joinery may be extended to various decorations both exteriorly and interiorly, as in architraves, bases, surbases, pilasters, columns, &c., as also in the linings of walls, or partitions, in the forms of boarding and wainscoting, and in the construction of stairs and hand rails.

For all these purposes the surfaces which are exposed to the eye ought to be made quite smooth, and the joints between every two separate pieces of wood perfectly close.*

Section I.

The best stairs are constructed with an opening in the middle of the stair formed by the ends of the steps, which are generally all in one surface, rising perpendicularly to the horizon from a given line on the floor, which line is called the *plan of the ends* of the steps, and the open space in the middle of the staircase is called the *well hole.*

The *hand rail* is a fence made adjacent to the well hole, raised to such a height above the steps and supported by vertical bars called *balusters*, as to prevent those who ascend or descend from falling through the well hole. In the formation of the straight parts the workman requires no directions; we shall therefore treat only of the construction of the curved parts, or of the curved part of a rail, and so much of the straight parts as not only give the proper direction or position, but also afford the best means of fixing the straight and circular parts together.

A body is said to stand over a given plan when a right line drawn from any point whatever in the outline of the plan perpendicular to the horizontal plane, can only touch the body thus raised.

A stair is said to make as many revolutions as the stories are in number through which the stair is carried, and all these revolutions generally stand over the same plan.

The hand rail is generally prepared in such a manner that the section of the rail made by a vertical plane drawn perpendicular to any tangent whatever, to the convex or concave side of the plan through the point of contact, may be a rectangle, and that the rectangle may have two sides perpendicular, and consequently two sides parallel to the horizon; moreover, that every two of those rectangular sections may have the same horizontal breadth. The figure of the rail having this property is said to be *squared.* A rail thus squared will have four visible sides or faces, of which two are cylindrical and stand immediately over the sides of the plan, and of which the other two are spiral surfaces, and cover the area of the plan between its outlines. The convex cylindrical surface when extended in plano ought to be everywhere of equal breadth.

The figure of the convex surface extended in plano is called *a falling mould.*

As the curved part of a squared rail is generally put together in two parts, so as to form the entire curved part, with the addition of a small part of the straight rail joining each extremity of the curved part, each part may be comprised between two parallel planes, of which one may be made to touch one of the spiral surfaces in three points, and the other to touch the other spiral surface at least in one point.

Then it is evident that the whole rail may be contained between two cylindrical surfaces and two parallel plane surfaces. Therefore the sections of the cylindrical surfaces in these parallel planes will be equal; and since the outlines of the plan of the rail are right sections of the cylindrical surfaces, we have only to find from the right section an oblique section of the two cylindrical surfaces in the same position as the two parallel planes would be when the rail is put in its proper position. A mould formed to such a section is called a *face mould.**

Example. In a semicylindric stair terminating with parallel straight walls, let *a b c d e f c, . . . a*, fig. 5, be the plan, the half of the rail over the circular part; the quadrant *b c d e f* being half the ground line of the semicylindric surface which contains the convex side of the rail, and the quadrant $\beta\gamma\delta\epsilon$, the ground line of the semicylindric surface, which contains the concave vertical surface of the rail, the right lines $a\,b$, $a\,\beta$, the groined lines of the planes containing the exterior and interior surfaces of the straight parts of the rail, and the right lines $a\,a$, $f\,\epsilon$, the ground lines of the vertical planes which contain the joints. Moreover, let a, b, ϵ be the ground points of three vertical right lines which contain the heights of the rail or distances from the plan to the under spiral surface; besides this are given the heights above these points to the under spiral surface of the rail to find the falling mould, and the face mould, as also to show the positions in which these moulds may be applied to the plank.

---

* In the operations of Joinery, the field of application of those extensive principles, to which the Art of Carpentry has been so much indebted, is narrow and not so generally interesting. We cannot, however, dismiss this subject without laying before our readers some of their further applications, and such as will be both advantageous and agreeable to the pursuits of the ardent student in the general knowledge of construction.

Among these the principles and construction of hand rails will be found of the greatest utility; we shall therefore invite the reader to direct his attention to that subject.

* Hence, if the piece of wood out of which a part of the rail is to be made, has its thickness equal to distance between the parallel planes, the rail may be cut out of the wood by applying the face mould on each side of the plank in its proper position; and having cut away the superfluous wood, so as to form the concave and convex cylindrical surfaces, it will only remain to apply the falling mould in its proper position, and then to form the spiral surfaces by means of the lines drawn upon the cylindric surface, from the falling mould, and the part of the rail thus squared, when set up in its situation, will arrange over its plan as required. All that is then required is to find the face mould and the falling mould.

The position of the plane of section may be determined by having given three points on the plan, and the perpendicular heights of the right lines standing upon these points to the under spiral surface of the rail.

From what has now been explained, it is expected that the reader will have his ideas sufficiently clear to comprehend the construction of hand railing.

The plan of a hand rail must be regulated by the plan of the stairs. The most general form of a staircase is that of which the vertical superficies of the walls is a semicylindric surface, joined at each edge by two plane surfaces, which if prolonged would be tangents to the semicylindric surface, and are consequently parallel to one another; the staircase is enclosed by a third wall, of which the inner vertical surface is perpendicular to the other two vertical surfaces which join the semicylindric surface. So that the plan of such a stair is in the form of the letter D. Fig. 4, plate vi. exhibits the two projections of a staircase and stair as that now described. The faces of the steps are all perpendicular to the interior vertical surface of the surrounding wall, therefore in the straight walls they are in parallel planes, and in the circular part they bend to the axis of the cylindric surface. Those steps in the cylindric part are called winders, and those in the straight part are called fliers.

In fig. 6, draw the right line A D, and in A D make A B equal to the breadth of one of the steps in the fliers. Draw B C perpendicular to A D, and make B C equal to the height of one of the steps. Join A C, and make B F equal to $b\,a$, fig. 5. In the right line A D, fig. 6, make B D equal to the length of the circular arc $b\,c\,d\,e\,f$, fig. 5, and draw D K perpendicular to D A. In D K make D E equal to the height of as many steps, and one more than the half of the circular part of the plan contains winders, and join E C. Cut off the angle at C by the curve G H K, so that C A and C E may be tangents to the curve at G and K.

The A G H K E is the under side of the falling mould. Draw the mixed line I J K equidistant from a mixed or compound line A H E, so that the distance between the two compound lines may be everywhere equal to the breadth of the developement of the convex cylindric surface of the rail, and these lines will form the falling mould required. Prolong B C to meet the under edge of the falling mould in H; and F G, B H, and D E are the three heights of the rail over the points $a\,b$, ϵ, fig. 5.

It now remains to find the oblique section of the cylindric surface by a plane passing through the three points of which a, b, ϵ are the feet. Join $\epsilon\,a$, fig. 5, and draw $b\,z$ parallel to $\epsilon\,a$. Draw the three right lines $a\,n$, $b\,x$, and $\epsilon\,y$ perpendicular to $\epsilon\,a$, or at any given angle with $\epsilon\,a$, so as to be parallel with each other, and make the right lines $a\,n$, $b\,x$, and $\epsilon\,y$, respectively equal to F G, B H, and D E, fig. 6; but as the object is to obtain the intersection of the plane, which contains the section to be found, this object will be found more conveniently by making $a\,n$, $b\,x$, and $\epsilon\,y$ a certain part of each line. Let therefore $a\,n$, $b\,x$, and $\epsilon\,y$ be each respectively equal to one-third part of F G, B H, and D E, fig. 6. In fig. 5 join $y\,n$, and draw $x\,z$ parallel to $y\,n$. Prolong $\epsilon\,a$ and $y\,n$ to meet each other in o, and through the points o and z draw the right line T U, which is the intersection of the plane which contains the section of the rail to be found. Through any convenient point T in T U draw the right line T V perpendicular to T U, and draw $\epsilon\,l$ perpendicular to T V, meeting T V in l. Draw $l\,l'$ perpendicular to T V, and make $l\,l'$ equal to D E, fig. 6, and in fig. 5 join E l', which prolong to W if necessary.

Then $a\,b\,c\,d\,e\,f$ may be considered as the base or right section of a cylindrical surface, T U the intersection of a plane cutting that cylindrical surface, and V T W the angle of inclination of that plane; it is required to find the sections of the cylindric surface upon this plane. This section will be found in the very same manner as that of an angle bracket, or angle rib of a cove ceiling, and the application of the moulds to the plank will be found in the very same manner as the application of the moulds to the boards in forming an angle bracket.

Thus let the oblique sections of both cylindrical surfaces be found, and let them be $a'\,b'\,c'\,d'\,e'\,f'$ and $a'\,\beta'\,\gamma'\,\delta'\,\epsilon'$. Join $a'\,\epsilon'$, and draw $p\,q$ parallel to T V, and at such a distance from T V as may be equal to the thickness of a plank sufficient to contain the rail, and let $p\,q$ meet $l\,l'$ in q. Draw $q\,r$ perpendicular to T W, and draw $\epsilon'\,r$ parallel to T W, also draw $r\,s$ perpendicular to $a'\,\epsilon'$ meeting $a'\,\epsilon'$ in s.

In fig. 7, plate vi., let L M O N be the edge of the plank, L P Q M the top, N R S O the under face. We shall call $a'\,b'\,c'\,d'\,e'\,f'\,\epsilon' \ldots a$, in fig. 5, the face mould. Apply the face mould in fig. 5 to the face P L M Q, fig. 6, of the plank, so that the points $a'\,\epsilon'$, fig. 5, may be upon L M, fig. 7, *viz*, ϵ upon t, and a, fig. 5, upon z, fig. 7, and draw Y the figure of the mould. In L M, fig. 7, make $t\,u$ equal to $\epsilon'\,s$, fig. 5, and in fig. 7 draw $u\,w$ perpendicular to L M, intersecting N O in v. Make $v\,w$ equal to $r\,s$, fig. 5, and draw $u\,x$ parallel to N O. Apply now the face mould so that the points ϵ', a', fig. 5, may be in the line $w\,x$, fig. 7, the point ϵ' being upon w, and the point a' upon x, and that the entire mould may be upon the face N O S R. Then the figure of the mould being drawn also upon this side of the plank, the two figures thus drawn will be true sections of the cylindrical surfaces required, and if the plank containing these figures be set up in its real position, the curve line $a'\,b'\,c'\,d'\,e'\,f'$, fig. 5, will fall over the ground line $a\,b\,c\,d\,e\,f$, and the curve line $a'\,\beta'\,\gamma'\,\delta'\,\epsilon'$ will fall over the curve line $a\,\beta\,\gamma\,\delta\,\epsilon$.

Having cut away the superfluous wood on the outside of the figures, the two helical surfaces may be formed by means of the falling mould, and what remains to be done will be understood by the workman.

The mitre cap of a rail is a piece of wood formed into a surface of revolution, in order to terminate a straight hand rail, and is generally employed when the stair has no well hole.*

In fig. 8 assume the point s' for the projection of the axis of rotation, and from s' with a radius equal to the radius of the great circle of the mitre cap describe the circumference $a'\,g'\,f'$ of a circle, and this circle will be the projection of the contour of the mitre cap. Draw $s'\,s$ in any convenient direction for the projection of the vertical plane which divides the rail and the mitre cap into two equal parts. Then the projections of the contour of the sides of the rail will be right lines, which will not only be parallel to the right line, which is the projection of the symmetrical plane, but will be equidistant from that right line, and on contrary sides of it: therefore, through any point s in ss' draw af perpendicular to ss', and make sa and sf each equal to half the breadth of the back of the rail. Draw aa', fg parallel to $s's$, meeting the circle $a'gf'o$ in a' and g and aa', fg will be the projections of the sides of the straight rail.

---

* The rail is mitred into the circular cap, which is of greater diameter than the breadth of the straight rail, and the two are joined together in such a manner, that, when finished, a vertical section may divide both the rail and the mitre cap into two symmetrical parts; and that this plane may pass through the axis of revolution of the mitre cap, and longitudinally along the rail; and that the back of the rail, after descending in a right line, may proceed in a curve until it becomes level, or has a horizontal tangent at the point where it meets the circular cap; and that the surface of the rail and the surface of revolution of the circular cap may meet each other in two vertical planes only; and that the intersection of the meeting planes may be in the longitudinal plane which divides the hand rail and the mitre cap each into two symmetrical parts.

Let the plan of the rail and the mitre cap be so projected that the axis of rotation of the mitre cap may be perpendicular to the plane of projection; then the plane which divides the part of the rail and the mitre cap each into two symmetrical parts will be projected into a right line, and the centre of the mitre cap will be projected into a point, and the contour of the mitre cap will be projected into a circle of which the diameter is equal to the great circle of the mitre cap. The point which is the projection of the axis of rotation will be the centre of the circle, which is the projection of the contour of the mitre cap, and the right lines which are the projection of the planes containing the mitre will be radii of the circle, provided these planes pass through the axis of rotation as they are supposed to do.

Let $abcdefru$ be a right section of the straight rail so placed with regard to the line af, that af may be the greatest horizontal dimension of the right section of the straight rail: hence the right lines in the section which are perpendicular to af will be in planes parallel to the plan which divides the rail and cap into two symmetrical parts, and therefore the projections of these planes and the ordinates of the right section of the rail will all be in right lines parallel to ss'.*

The figure $aa'af'gf$ may be considered as the projection of the surface S, as well as the projection of the rail and cap, and $a'f'$ may be considered as the intersection of one of the mitring planes in the surface S; therefore the ordinates upon $a'f'$ will be equal to their corresponding ordinates upon af. Hence through any point p whatever in af draw the right line pp parallel to ss' to meet af in p. Draw pb perpendicular to af meeting the curve or outline of the right section in b, and draw $p'b'$ perpendicular to $a'f'$. Make $p'b'$ equal to pb; then the points a', b', f are in the curve of the circular cap. In the same manner may be found a number of points through which the curve may be drawn with sufficient accuracy; this being done $a'b'c'd'e'f'v'u'$ is the section of the mitre cap required.

SECTION II.

Hoppers of mills.

The construction of columns and the hoppers of mills in wood, whether mitred or dovetailed, depend upon that principle of the trehedral in which the two right faces are given, to find the inclination opposite to one of them or adjacent to the other, and as such subjects frequently occur in practice, one or two examples will be useful to the student in this branch of the art of construction.

Example. Fig. 9 exhibits the two projections of a hopper joined together in the form of a regular square pyramid. The horizontal projection containing the plan being parallel to the square base of the pyramid, and the vertical plane containing the elevation being parallel to one of the edges of the base and perpendicular to the adjacent edges. The base will therefore be projected into a square, and the elevation into an isosceles triangle. Let the plan be A B C D and the elevation E F G; the right line E F being the elevation of the base A B C D. In the plan draw the diagonals A C and B D intersecting each other in the point H and draw H i perpendicular to H B. Make H i equal to the height of the pyramid hG in the elevation, and join B i.

We have now given the angles of the two right faces H B i, h B C of a right trehedral, to find the dihedral angle opposite to the right face H B C.

From any convenient point H in the diagonal B D, draw H j perpendicular to B i meeting B i in j, and draw H C perpendicular to B D meeting B C, or B C prolonged in C. In B D make H k equal to H j and join k C. Then H k C is the angle of the mitre, and the double of the angle h k C will give the angle of the abutment of the dovetail joint.*

Fig. 10 exhibits the two projections of a regular octangular pyramid according to the foregoing positions, and as the diagram will agree with the same explanation it would be unnecessary to proceed further. The accented letters in the two diagrams 9 and 10 are affixed to pyramids of less height, and show the method of finding the angle of the mitre more clearly.

By this means a solid of revolution approaching in figure to the frustum of a right cone may be constructed with a series of thick battens of wood.

For the frustum of a pyramid of which the bases are regular polygons may be formed so as to be easily converted into that of a right cone. By increasing the number of sides, and by making the planes of the sides at equal angles with the planes of the bases, this conversion will be more easily effected.

And since this frustum is evidently the figure of a roof hipped on all sides, having the planes of the covering at equal angles with the plane of the horizon, and the outer edges of the tops of the walls in the form of a regular polygon, the angle contained by any two adjacent planes of the sides of the pyramid will be found in the same manner from the angle made by two sides of the polygon, and the inclination of the face of the pyramid to the plane of the base, as the angle at the hipped edge of a roof is found from the angle made by the two adjacent walls, and the angle made by any of the sloping sides of the covering, and the plane of the top of the walls.

With respect to the polygonal frustum under consideration, the angle contained by the planes of two adjacent sides being found, the half of it will be the dihedral angle made by the outer face and the surface of the edge of each batten. The length of each batten at the edge will be found in the same manner as the length of the hip line of a roof, and the breadth of a batten at each end will be equal to the side of the polygon at the corresponding end.

---

* Let us now suppose a surface passing through the solid of the rail and containing the right line af to be called the surface S; and let us suppose a vertical plane intersecting the surface S, and passing through any point whatever in af parallel to the plane of symmetry to be called the plane P, and let the intersection of the plane P and the surface S be called the intersection I; then let the intersection I in the plane P divide the section of the rail in the plane P into two such parts, that the part between the intersection I and the back of the rail may be everywhere of the same breadth; then every right line perpendicular to the surface S, comprised between the surface S and the curved surface of the cap, will be equal to the right line in which the cylindric surface which contains the perpendicular, and of which the axis of rotation is also the axis of that cylindric surface, meets one of the planes of the mitre.

* Sometimes for want of room it may not always be convenient to use the entire distance hG, figures 9 and 10, and since all that is required is to find the angle H B i of the vertical face; therefore in the case of more room being required, draw from any convenient point s in the elevation sm perpendicular to E F meeting E G in m, and draw sn perpendicular to E F meeting B D in n. Draw no perpendicular to B H, and make no equal to sm. Join Bo, then Bo and Bi are in the same right line; hence hBo and hBi make the same angle. Draw ns perpendicular to Bi meeting Bi in s, and in B H make nt equal to ns. Draw ne perpendicular to B H meeting B C in e, and join te. Then the angles ntC and nte are equal.

The battens being all properly diminished, and the surfaces of the faces and edges made to form the angle required, the parts when joined together will be the frustum of a pyramid, which will be easily converted into that of a right cone by reducing the angles and thereby leaving a regular curved surface in place of them.

Hence the shaft of a column may easily be constructed upon this principle; first, by making it in the form of the frustum of a pyramid, and then by rounding off the angles.

The following observations on the application of the principles to practice will be found of signal use to the young architect, builder, or workman.

A working drawing is a representation of the whole or of some part of a building on a plane surface, and may either be a plan or elevation, a section or a developement of the parts required to be put in execution. The constructive lines in Carpentry are generally developements of certain difficult parts of an object or building. A developement, though drawn upon the same plane, consists of one or more sections of the object in different planes, these sections being supposed to be raised to the proper angles which they make in the object itself upon certain lines which are in the plane upon which the drawing is made.

Having fully explained the theory and practice of Carpentry and Joinery, the reader will now be prepared to apply the principles of this theory to real buildings. In conclusion, it may be useful to give a short connected abstract of the whole principles before enumerated, and to point out their applications to practice.

Developable surfaces of cylinders and cones are not only applied to the formation of arched soffits in the apertures of doors and windows, but also to the coverings of circular roofs and domes. Pliable moulds made with such surfaces are used in Joinery for the construction of hand rails, and in masonry to form the conical beds of the stones of a dome, and the intrados of the stones of an oblique arch.

The sections of solids are applied in constructing the angle ribs, brackets of roofs, groins, and of coved ceilings.

The trehedral is applied in roofing to find the angles at the junctions of the timbers and the backings of the hip rafters, as also in masonry to form the beds of the stones of oblique arches.

FORTIFICATION.

Definition of the Art or Science of Fortification.

Fortification, in the strictest acceptance of the term, is usually limited to the *Art* of constructing such works of defence, as may enable a body of men to maintain the possession of a city, or of any military post or line of country, against the assaults of a superior numerical force. But in a more enlarged sense, Fortification embraces also the *Science* of attacking and defending the constructions which it creates; and in this view, therefore, its uses involve a very principal part of the whole business of warfare. The Art of fortifying has often been eulogized, by its professors at least, as that exercise of martial skill which merits the unqualified applause of humanity: by reason of its being employed for the protection of the feeble against the oppression of the strong. The severer judgment of History will detract from much of this boast. Fortification, at the most favourable estimate, must only share the praise or reproach which justly attaches to the military Art in general, according as it is honoured or disgraced by the purposes to which it is devoted. Defensive structures were, doubtless, originally the resource of the weak: but they have been full as often erected to rivet the yoke of conquest and servitude, as to cement the proud security of a free people; nor, in the confusion and frequency of international wars, would it be easy to measure the moral benefits of an Art which, obeying the shifting vicissitudes of human events, is used alternately to resist invasion and to consolidate tyranny.

Proposed division of the subject.

Such considerations may be safely abandoned to the idleness of professional enthusiasts: they tend to no practical result, and suggest no lessons of improvement. As a preliminary to any attempt to give an acquaintance with the general principles of Fortification in its present state, it is far more interesting and useful to trace the progress—or, as a lively foreign writer has termed it, the Natural History—of the Art through its connection with the military and political fortunes of Empires; and before, therefore, we enter into some analysis of the existing principles of warlike constructions and the established rules of Science by which they are assailed and defended, we shall endeavour to prepare the reader for a clearer comprehension of the subject, by a rapid sketch of the changes which the method of fortifying has undergone in different Ages of the World.

PART I.

HISTORY OF THE ART OR SCIENCE.

CHAPTER I.

Fortifications of the Ancients.

Obvious origin of Fortification.

In this retrospect to the earliest known modes of defence, we shall not imitate those Writers who have imagined it necessary to elucidate with oracular wisdom the origin of Fortification itself. Unquestionably we shall not deny, and still less shall we proceed to prove, the grave and palpable truism which such profound reasoners have laboriously enunciated:—that the Art of fortifying owed its primitive necessity and its rise to the violence and the wickedness of mankind. We may be content with the assurance, that the same want of individual security against the oppression and rapine of the stronger, which in the rudest stages of Society kept men united in families and communities, would dictate the first expedients for collective defence; that the same Art which reared the first hovels for human habitation, would prompt the idea of encircling the congregated dwellings of the Tribe for the public security with a wall or a fence of similar materials and structure. The nightly depredations of wild beasts, the incursions of human enemies hardly less ferocious, would equally suggest to the most untutored Savages the necessity of such an enclosure for the protection of their flocks and herds, their women, their children, and themselves. In a word, the impulse of self-preservation, which is implanted by Nature in the human breast, would teach men in their wildest state to oppose to the fierce inroads of brute force such obstructions, as might place their lives and property in security from sudden destruction, and compensate for disparity of numbers and physical strength. Those obstructions, whatever might be their form or kind, were, in effect, Intrenchments; and the craft which disposed and fashioned them already constituted the Art of Fortification. That Art may therefore be said to have originated with Society itself; the first expedients for its improvement would be contemporary with the earliest efforts of human ingenuity and contrivance; and, it need not be added, that its principles of construction have always kept pace with the general progress of Civilization and the discoveries of Mechanical Science.

First expedients for defence.

Their materials and form.

It would not, perhaps, be very important to determine with exactitude, even if we possessed the means of so doing, the nature and form of the very earliest fortifications. But we shall probably collect a sufficient idea of their qualities, by the analogy which may be supposed to subsist between them and the rudest essays of the Art, observable among the savage people of different quarters of the Globe in recent times. The materials of the most ancient and simple fortifications were, no doubt, those on which, indeed, the modern engineer, with all his science, is still obliged, in his field operations, chiefly to rely:—earth and wood. To clubs and stones, the first offensive weapons among Barbarians, a bank and ditch, or a single row of strong stakes, or trunks of trees, might offer a more than sufficient resistance. But as soon as the assailant learned also to assist his animal strength with even the simplest expedients of Art, additional solidity and ingenuity became requisite for security in the construction of works of defence.* In New Zealand, Cook observed the *hippahs*, or village-forts of the natives, placed on heights and in commanding situations, but consisting of only a single enclosure of trunks of trees strongly and closely set on end in the ground, with a slight inclination inwards. This fence was lined at intervals by interior platforms or stages raised to within three or four feet of its summit, from which its defenders, themselves covered to the breast, could hurl their stones and javelins on the assailants below. At the outset of the conquest of Mexico, Cortes and his followers (A. D. 1519) found the defences of Tobasco, a town of some size on the American Continent, yet more simple in construction than those which we have instanced among the Savages of New Zealand. That Indian fortress was composed of only a circular enclosure or stockade of large trunks of trees set upright, with small apertures through which arrows might be discharged.† The ancient intrenchments of Kani Sigeth, and Temiswar, in Hungary and Turkey, as they existed so late as A. D. 1700, are said to have afforded a specimen of barbarian Art but a step more advanced. These consisted of a double line of strong piles, having the interval between them filled with the earth of the ditch which had been excavated in front; the outer row of piles being left highest, to serve as a sort of parapet or breastwork for the defenders on the terrace or rampart. A remarkable similarity to this construction was shown in the intrenchments of the Burmese during our late war in Ava. Their common breastworks were formed of a double line of stakes or hurdle work, the intermediate space of which was filled with earth; and their stockades or palisaded redoubts from ten to twenty feet high, whose assault in an uncleared and difficult Country cost the lives of so many of our gallant Countrymen, were built much in the same manner as those ancient Hungarian works.

Progress of the Art.

Walls and towers of masonry.

See plate ii. fig. 2.

Such examples may suffice to exhibit the natural infancy of the Art in all Countries and Times. The next improvement in military defence would obviously be coeval with the first employment of masonry in Civil Architecture. Against the assaults of an enemy unprovided with ponderous missiles, a simple wall of stone or brick would form a more lofty and durable rampart than intrenchments of earth or wood; its height would increase the difficulty of escalade; and the invention of battering engines for its demolition would only impose the necessity of an additional thickness and strength in its construction. But the defence was still extremely defective, as long as the besieged, from behind the summit of their wall, were altogether unable to see the assailants at its exterior base; and this inconvenience produced the expedient of a flanking or side defence:—a condition that may be said to form the main principle of the Art. To obtain a flanking defence for the wall, massive towers of masonry were built at all its angles and on each side of its gates; and these towers besides being made to project for that purpose in front of the wall, were constructed of superior height so as to command or overlook every part of it. The use of towers, indeed, in Fortification may be pronounced of immemorial antiquity: for there are innumerable notices of their existence on the walls of fortresses in the earliest records, sacred and profane: in the Historical books of the *Old Testament*, and in the *Iliad*. In later Ages they were made sometimes square, hexagonal, and octangular: but the preference was generally given to the circular over any of these forms, as best adapted to resist the shock of battering engines.*

Immemorial antiquity of such defences.

Machicoles

Another invention of uncertain but less remote date was employed to increase the power of the *direct* defence, and to enable the besieged to see down to the base of the towers and walls. Along the summit of all the works, and overhanging the main mass, was constructed a narrow gallery, supported by *corbels* or stone brackets, through the pierced floor of which every kind of missile might be showered upon the heads of the assailant below, who should attempt either to scale or undermine the walls. These *machicoles*, or projecting galleries, still presented to the country the parapet or battlement that always crowned the walls, with apertures for the discharge of arrows and javelins at the assailants in front; and a lower gallery also often ran through the thickness itself of the wall near its top, pierced with loopholes for the same purpose, and arched and open towards the interior.† A wide and deep moat, either filled with water, or dry where the level of the Country denied that resource, swept round the whole circuit of the walls, and completed the defence.

and moats.

For an idea of the general appearance of ancient fortresses, see plate i. fig. 1.

Such, whatever variety there might be in the details, and whatever gradual improvement in the process of construction, continued the general character of fortresses and the principles on which their defence was regulated, from almost the earliest epochs of authentic History even until after the invention of gunpowder. The walls of Pæstum, which are pronounced by the best Classical Antiquaries to belong to a period far more remote than the Age of Grecian civilization, are surmounted at intervals with the circular tower; and these stupendous remains do not differ greatly as fortifications from the structures of much later times. This common agreement of the modes of defence, which seems to have obtained at a very distant Age throughout the Western parts of Asia, and the European and African shores of the Mediterranean, may justify the opinion that the first improvements in Fortification, as in other Arts, were derived from the East. But whatever was the origin of the general system of fortifying among the civilized Nations of Antiquity, it was from the vigorous intelligence and warlike spirit of the Grecian and Roman mind, that it attained all the perfection of which it was susceptible, whether in attack or defence; and it is in the records of the achievements and knowledge of those People alone, that we can gather the traces of the ancient Science.

It would, however, be to little purpose to fatigue the

---

* As an ancient example of this first improvement in Fortification may be mentioned the strong-hold of the Drilians, a People who inhabited the shores of the Euxine: this is described by Xenophon (*Anabasis*, lib. iv.) as surrounded by a ditch and rampart, on which were palisades and wooden towers.

† B. Diaz de Castillo, *Hist. de la Conquista de la Nueva Espagna*, c. 34.

* Vitruvius, book i. c. 5.

† Such a passage still appears in the remains of Aurelian's walls at Rome. Newton *on Vitruvius*, lib. i. c. 5.

A modern traveller describes a similar kind of gallery with apertures for the discharge of missiles in the ruins of the walls of Tirynthus near Argos, a construction of great antiquity. Hughes, *Travels in Greece*, &c.

Fortifications of the Greeks and Romans.

general reader with minute details, even from Grecian and Roman examples, of the ancient system of fortifying; and a very few further remarks on its conditions will be all we shall offer. In the tracing or ground-plan of the works, it does not appear that any fixed rules were followed, as in modern constructions. The configuration of the walls was usually determined by the accidents of the site; or if any general disposition was preferred, it seems to have been merely an irregular succession of salient (or projecting) and re-entering angles, flanked by towers. This arrangement, from its frequent adoption, must have been generally considered most advantageous for an obstinate defence: though Vitruvius[*] recommends the outline which most resembles a circle, and proscribes very salient angles as easiest to attack and most difficult to defend. Under any circumstances it was a natural rule that the towers should not be further apart than the range of the ordinary missiles of the infantry in order that every part of the intervening walls might be covered by their flanking discharge.[†]

Configuration,

height, and

The height of the walls seems never to have been determined by any general rule, and differed in all sorts of examples and circumstances. Herodotus[‡] gives to the ramparts of Babylon the enormous elevation of three hundred and fifty feet. Xenophon[§] says the works of Larissa on the Tigris were one hundred feet high, and those of the Median wall near Babylon of the same elevation.[||] But, without multiplying citations, it may be sufficient to observe, that modern commentators have been led to consider about one hundred and twenty feet as the mean height of the ramparts of Antiquity; and it is only in Asiatic constructions, which seem usually to have been formed on more gigantic proportions than those of Europe, that many instances are recorded of a greater elevation. The thickness, like the height, of walls was various: but to afford space for the passage of armed men on the summit behind the parapet or battlements, and through the lower galleries, as well as to resist the assaults of the battering ram, it could scarcely in any case be less than eight or ten feet. But it was certainly often far greater; nor for the placing and working of the defensive engines could that breadth have sufficed. It has been disputed, indeed, in what manner these engines were disposed, and doubted whether they were ever placed *on* the walls: but though such as threw stones might cast their missiles from interior terraces or mounds over the walls like the modern mortar, there were others, for the discharge of darts and iron-pointed beams, which must assuredly have been used, with a horizontal or *point-blank* direction, through apertures on the summits and in the thickness of the works.[¶]

thickness of their walls.

Breadth of rampart required.

It was doubtless for the purpose of obtaining a more spacious rampart for the placing of these engines, as well as for increasing the power of resistance to the battering ram, that the expedient of raising an inner wall of masonry parallel to the outer, and filling the interval with rammed earth and rubbish, was often adopted. Thus the walls of the Piræus and of Byzantium were twenty feet broad; those of Nineveh thirty feet; and those of Babylon, which are described by Historians as seventy feet in thickness, were probably built in this manner. The ramparts of Bourges were forty feet thick; and Cæsar has detailed their mode of construction, which he declares was common to almost all the Gaulish cities. They were built of trunks of trees laid in horizontal rows, two feet asunder across the thickness, and of alternate courses of stones and well-trodden earth; and the outside of the rampart was clothed with a thick wall of masonry, in which the ends of the beams were imbedded. This mode of building was admirably adapted for a good defence; because the timber resisted the efforts of the battering engines, while it was secured from conflagration by its admixture with the earth and stone.[*] Vitruvius recommends the use of scorched olive piles for the same purpose; as that wood is unaffected by the weather, by rot, and by age. But in the most massive constructions, he advises the introduction of transverse walls to bind the external and interior faces of the rampart, disposed between them either perpendicularly like the teeth of a comb, or obliquely in the manner of those of a saw.[†]

Double and triple circuit of walls.

When a city happened not to be advantageously situated for resistance, or when its wealth and importance suggested a more elaborate provision for defence than a single circuit of towers and walls, a double or even triple envelope of works was constructed. Of these we have instances in Jerusalem and in Rhodes; while Ecbatana, the Capital of Media, was surrounded with no fewer than seven enclosures of rampart.[‡] A citadel in the interior of a fortress, or formed on the least accessible part of its circuit, was as common a resource, for securing a last refuge to the garrison, or for overawing the citizens themselves if disaffected, as in modern times. And, not unfrequently, the several quarters and suburbs of a large city formed so many distinct fortresses: while sometimes a chain of detached works covered the heights which commanded the approaches to the place, or, in maritime situations, defended the entrance of ports, or the mouths of rivers.

Example of Syracuse.

B. C.
413.
396.
212.

For a single example, exhibiting all these provisions of defence, we need only cite the fortifications of Syracuse, which Nature and Art had conspired to render one of the strongest places of antiquity, and which deserves particular notice in Military History for its resistance in three memorable sieges to the arms of the most warlike and scientific assailants of the times—the Greeks, the Carthaginians, and the Romans. In all these sieges, of which the first and last (by the Athenians under Nicias, and by the Romans under Marcellus) must be familiar to every reader, the defence may be declared to have been successful: the besieging armament of the Carthaginians under Imilcon, like that of the Athenians under Nicias, was repulsed and destroyed;* and it was not until the genius of Archimedes had baffled the assaults of the Romans, and long after they had been compelled to convert the siege into a blockade, that Marcellus carried the place by surprise. The main-land City of Syracuse was seated on the Northern side of its fine port, at the entrance of which lay the Island of Ortygia, (*a*) separating it into two harbours; the lesser, or that between the Island and the City, being thus divided from the rest of the bay. Ortygia constituted the chief maritime defence of the City; it contained the citadel and arsenal, insured the command of the two ports, and was therefore altogether so much regarded as the key of the whole City, that the Romans, after obtaining possession of the place, never suffered a Syracusan to inhabit it. Between the first and second sieges, Dionysius the Elder built a dam from the main-shore to the Island across the inner entrance of the little harbour, by which it had communicated with the great port; while the passage from the sea was closed by a wall or pier, with gates which admitted only a single vessel at a time. The little port, which was capable of containing sixty of the largest war-galleys, was thus, in fact, completely embraced within the fortifications. The entrance of the great port from the sea was likewise, at a later period, defended as well by a strong fort (*f*) on the Southern main-land promontory of Plemmyrium, as by that end of the Island; while the castle of Olympiæum (*g*) at the bottom of the bay further commanded its interior shore. The main-land City of Syracuse itself was composed of four distinct quarters, each fortified separately, while the whole was enclosed by a common envelope of lofty walls and towers: Achradina (*b*) facing the sea to the East, and forming the whole lower breadth of the City; Neapolis (*c*) and Tychē (*d*) adjoining it, and presenting their exterior walls to the "great port" and the North respectively; and Epipolæ (*e*) crowning the Westward heights. The security of the last quarter, which was almost encircled by nature with a chain of crags and precipices towards the country, had been strangely neglected; so that the Athenians, in the first siege, were suffered to establish themselves in it: but it also was fortified by Dionysius with such strength as to cover the lower quarters of the City, and to render the heights themselves, and the whole place, impregnable from that side.

---

[*] *Ubi suprà.*

[†] This range probably did not, in general, exceed one hundred feet; and for one example we find in effect that the distance between Cæsar's towers in his lines before Alesia (not at the siege of Bourges as Newton has erroneously stated) was eighty feet. *De Bello Gallico*, lib. vii. The wooden towers constructed to strengthen the intrenchments of armies were, however, frequently further asunder; those raised by Philip of Macedon at the siege of Thebes in Phthiotis were one hundred paces from each other. Polybius, lib. v. c. 9.

[‡] Lib. i. c. 98.

[§] *Anabasis*, lib. iii.

[||] *Idem*, lib. ii.

[¶] Among the Romans there was an express distinction even in terms between the *embrasures* or mere openings in the battlements at the top of walls, and the *port-holes*, or apertures, with which the successive stages of the towers were pierced: the former were called *crenæ*, the latter *fenestræ*. From Cæsar we find positive evidence that, in towers of attack, engines were placed which discharged their missiles through port-holes. In the tower raised at the siege of Marseilles, it is said, *fenestrasque quibus in locis visum est, ad tormenta mittenda struendo reliquerunt. De Bello Civili*, lib. ii.

See pl. ii. fig. 3.

Ancient modes of attack.

After this brief and general explanation of the ancient manner of fortifying, it is necessary to offer a similar illustration of the mode in which the attack of places was conducted. In the ancient, as in the modern Science of Fortification, the system of attack was naturally regulated according to the method and form of defence which it was requisite to overcome. In the absence of any sufficient means of forcing a passage through a solid rampart too lofty for escalade, the first expedient, perhaps, which might present itself to an assailant would be, to commence a mound or bank of earth before the place, to increase and carry forward the mass until it touched the walls, and was raised to the level of their summit, and thus to pour his whole force of numbers *over* the defences upon the besieged. Such, accordingly, we find was the earliest mode of attack which is recorded in the authentic History of Mankind; and such, indeed, continued to be one of the common expedients of assault, even in the most scientific Ages of Classical Antiquity. A passage in Holy Writ seems clearly to point to the existence of this mode of attack, even as early as the Age of Moses, fifteen centuries before Christ, where the Israelites are commanded, in besieging a city, to cut down such trees only as are not fruit-bearing, and to "*build bulwarks* against the city" until it be subdued;* but yet more expressly the denunciation against Sennacherib, King of Assyria, that he "should not shoot an arrow into Jerusalem, nor come before it with a shield, nor *cast a bank against it*,"† proves that, at least seven hundred years before Christ, this was the ordinary process of a siege in the Countries of the East.

2. By battering and missile engines.

At what period the next contrivance which might occur to a besieger was invented—that of machines for effecting an entrance into the place by beating down a part of the walls, or the use by both parties of great engines for hurling masses of stone and other missiles upon their adversaries, it is difficult to determine. These inventions were probably not known in the Age of Homer, since no mention of them is made in the *Iliad*, where their use would naturally have found a place in the vivid picturing and minute description of the combats before the walls of Troy. But in Sacred History we find them numbered, within four hundred years after the era of the siege of Troy, among the means provided for the defence of Jerusalem by King Uzziah, (about B. C. 800,) who "made in Jerusalem engines invented by cunning men, to be on the towers and upon the bulwarks, to shoot arrows and great stones withal."‡ It is, however, probable that such engines were not then for the first time constructed; and we may therefore refer their invention to an intermediate period between the collection of the Homeric Poems and the reign of Uzziah in Palestine, that is, about a thousand years before the Christian Era.

Process of an ancient siege.

After these references to the obscure practice of remote Antiquity, we pass at once to the mature state of the Science of offensive and defensive Fortification, as exhibited in Grecian and Roman warfare. It would far exceed our limits, and otherwise, indeed, it would not answer any useful purpose, to mark with chronological precision the fluctuations of the Science during what are commonly understood as the Ages of civilized Antiquity, from about the great Persian invasion of Greece to the fall of the Western Empire of Rome; and, therefore, in briefly describing the process of an ancient siege, we shall refer less to examples of any particular epoch, than to the general perfection which was attained in the whole period. In commencing a formal siege on a great scale, the first operation of the assailants, or mode of investing a city, was to draw round it a double line of earthen intrenchments or ramparts: the one facing the country, the other the place; and the intermediate space forming the camp, and containing the troops, the

Lines of circumvallation and contravallation.

Diodorus Siculus, lib. xiv. c. 61—73.

* *Deuteronomy* ch. xx. ver. 20.

† 2 *Kings*, ch. xix. ver. 32. So also an expression in Jeremiah identifies the sense of the two passages above quoted: "*Hew ye down trees and cast a mount* before Jerusalem." ch. vi. ver. 6.

‡ 2 *Chron.* ch. xxvi. ver. 15. We believe that a passage in *Ezekiel*, about two hundred years later, contains the earliest express mention by name of the battering ram, that is any where to be found. *Ezek.* ch. iv. ver. 2.

engines, and the whole *matériel* or stores of the besiegers. The object of the outer circuit, or line of *circumvallation*, being to prevent the introduction of supplies to the garrison, or the relief of the place by an army from without; that of the inner, or line of *contravallation*, to confine the besieged to their walls, and secure the camp from their sallies. Against a place of great strength, or whenever the design was rather to reduce the besieged to the necessity of surrendering by the slow operation of famine, than to carry their defences by rapid assault, both the lines of circumvallation and contravallation were built with flanking towers at intervals, like regular defensive fortifications; and this laborious and tedious process of permanent blockade was, in fact, only the partial or entire enclosure of the fortress besieged within a second of similar construction. The distance of the circumvallation from the place was usually from nine hundred to one thousand yards; and both Greeks and Romans seem in all cases to have given great care and solidity to the formation of their intrenchments. At about six hundred yards from the place, a numerous guard was usually placed to repel sallies and protect the progress of the attack.[*]

Manner of approaching the walls.

Modern controversy raised on the subject.

Theory of the Chevalier de Folard,

Covered by these supports, the assailants, if an active siege were intended, began to carry forward their various works and engines of offence towards the walls. These were the mounds or *aggeres* already noticed; covered lines or galleries of approach and communication, being either excavated trenches or, more commonly, blinds of carpentry, hides, &c. the *vineæ* of the Romans; subterranean passages or mines; balistic and battering engines, the principal of which we shall enumerate; and, lastly, movable towers and other covered buildings, composed of strong timber, hides, haircloth, &c., on rollers and wheels. On the exact nature and form of several of these processes and constructions, modern opinions are much divided; and the laborious zeal of commentators has vainly endeavoured to illustrate satisfactorily descriptions of the ancient Writers, which, in the absence of plates, are necessarily obscure and uncertain, and which very few sculptured trophies or other monuments have survived to explain. In the last Century, particularly, the conflicting judgment of the military world was curiously excited in a controversy, which was first produced by the theory of the celebrated Chevalier de Folard. That enthusiastic soldier and devoted antiquary, with some Classical learning, and much professional knowledge, but with still more Imagination, endeavoured, in his Commentary on Polybius, not only to demonstrate the superiority of the Ancients in the whole Art of War, but to depreciate the efforts of modern strategical Science into a mere imitation of their principles and practice. In his theory, therefore, the operations of a modern siege seemed but the copy of the ancient attack: the balistic engines were disposed by his fancy, like batteries of cannon and mortars; the *vineæ* were the parallels and approaches of our modern trenches; the *aggeres*, cavaliers or raised intrenchments; and the mines similar in construction and purpose, to the appalling expedients of these gunpowder Ages.

Impugned by Guischardt.

The theory of Folard was assailed after his death by Guischardt,[*] a Dutch Officer of equal learning and cooler judgment, who exposed the extravagance of many of his conclusions, and established a superior reputation for accuracy and success as a commentator on the Military Art of the Ancients. In the degree in which he strained many passages from the Classical Authorities to the establishment of a favourite theory, no one, we believe, now doubts that Folard was wrong: but Guischardt, it can as little be denied, was led, in the usual eagerness of refutation, to the opposite extreme of error; and, in the conduct of sieges, at least, there are many more traces of coincidence between the ancient and modern practice, notwithstanding the vast change effected by the discovery of gunpowder, than he has always chosen to admit. In both, the object may be considered generally as the same, to effect a breach in the walls of the place; the aid of engines for the discharge of missiles was employed by the Ancients, like batteries of cannon and mortars in the modern parallels, to cover the progress of the attack, to ruin the defences, and to drive the garrison from the ramparts; and there was a close similarity in the object of the *vineæ*, whether galleries or trenches, with that of the parallels and approaches by the *sap*, in our times. The inferiority of the ancient means of attack to those of defence, is a far more remarkable distinction from the state of the modern Science, than is contained in any difference as to the mere order and design of the siege.

Aggeres

The nature and object of the ancient *aggeres*, or offensive mounds, we have already sufficiently explained. They were composed of earth, stones, timber, and all kinds of rubbish which could be collected; and constructed of immense mass and height with a labour and celerity—by the Roman legionaries especially—of which modern troops would probably be found altogether incapable. The *agger*, for example, raised by Cæsar's army at the siege of Bourges, was three hundred and thirty feet long or broad,[†] and eighty high; and he tells us that this huge work, notwithstanding the severity of the cold and perpetual rains, was completed, and advanced almost to touch the ramparts of the place, in twenty-five days. On the *agger*, the movable towers and balistic engines were placed, to overlook the walls and cast missiles upon the defenders; and the whole front of it was frequently screened with a strong blind of carpentry, covered with hides, hurdles, &c., to protect the assailants from the missiles of the garrison. At the siege of Jotapata by Vespasian, no less than one hundred and sixty engines were ranged along the *agger*; and several towers of carpentry were in the sequel also placed on it.[‡] Finally, it should be observed that in some cases more than one *agger* was raised against the walls: as at Marseilles, where Cæsar's troops attacked two of the fronts of the place.[§]

Vineæ.

Of the *vineæ*, however composed, we may be contented to assert, that they were certainly the works of communication and approach which the Ancients employed in their sieges. The manner in which the term is used by the Latin Authors is often vague and indefinite; nor shall we stop to weigh the opposite arguments in the antiquarian schools of Folard and Guischardt on their nature. There can be no doubt that they were frequently mere raised galleries of carpentry, hurdles, hides, &c., as above noticed; and that they were sometimes movable sheds on rollers and wheels. But it is equally undeniable from several passages, that they were at least sometimes, as Folard has asserted them to have been usually, excavations like the modern trenches. Thus, for an example of either kind, it may, in the first place, be noticed that at the siege of Echinus in Thessaly by the last Philip, where the attack was made against two towers and the wall between them, the besiegers erected a tower of timber, covered by hurdles, opposite to each of those of the town, and of the same height; and between them was a connecting gallery similarly formed. From the camp to each tower was also a covered gallery; and all these galleries served to conceal the communications of the besiegers. A battering ram was placed on the ground-floor of each tower, and three batteries of *balistæ* were placed in front of the gallery between them.[*] But, on the other hand, we learn that, at the siege of Lilybæum, during the first Punic War, when the Romans invested both sides of the town, they connected their two camps by an intrenchment;[†] and we find that, at Dyrrachium, Cæsar carried forward his approaches against Pompey's lines, by works which unquestionably corresponded to the modern trenches[‡] or excavations for cover. That lines composed of the *vineæ* were often drawn opposite to the walls, where *aggeres* were not used, something in the manner of modern parallels of trenches, to contain troops for checking the sallies of the garrison, and covering the circuit of communication, seems also most probable, though there is no evidence that such was, as in modern Science, the established and regular principle of attack: but whether by such *vineæ* or covered lines, and approaches, are in every case to be understood either raised galleries of timber, &c., or sunken trenches of earth, is a mere idle quarrel of words.

---

Mines.

Though at what time mines were first applied to the attack and defence of fortresses is uncertain, there is evidence of their familiar use by the Ancients as early as the Age of Herodotus; and in the more advanced state of the Military Art we find them employed almost invariably in sieges. In the memorable defence of the little city of Platæa, in the Peloponnesian War, (B.C. 429—7,)—the first siege, as Mitford has observed, of which any connected detail remains in the annals of mankind,—Thucydides relates[§] the attempt of the garrison to undermine the *agger* of the besiegers; and, on the other hand, the story in Livy,[‖] of the mode in which the Romans effected their entrance into Veiæ, (about B.C. 393,) after a ten years' siege, by the mine, is in the memory of every schoolboy. The capture of Gaza by Alexander may suffice for a later example[¶] of the successful use of the same process; and, in a subsequent Age, the walls of Palæa, in Cephalonia, and of Thebes, in Phthiotis, when besieged by the last Philip of Macedon, were undermined to the extent of two hundred paces in length.[**]

Counter mines.

Nor were the preparations of the besieged, either to arrest the subterranean approaches of the assailants, or to employ the same expedients against them, always deferred to the hour of danger. Vitruvius[*] mentions the construction at Apollonia of something like a system of defensive, or *countermines*, carried out to the distance of a bow-shot from the walls, to discover the subterraneous approaches of the besiegers. In these galleries were suspended brazen vases, which resounded at the blows of the enemy's iron tools in their vicinity, and showed in what part their miners were at work. These contrivances thus answered the same purposes as we shall find the listening galleries of the Moderns, and directed the engineer of the garrison where to drive out his galleries to meet the enemy, and destroy his workmen from above with caldrons of boiling water, pitch, &c. The introduction of torrents of water and barrels of burned feathers, and other suffocating mixtures, into the mines of an opponent, was also a common expedient of destruction. Finally, it may be observed, that at Gamala in Judæa, during the war of Vespasian against the Jews, Josephus[†] appears, by his narrative, to have prepared, while in the service of his Countrymen, a regular system of countermines for the defence of that fortress, which were used with considerable effect against the approaches of the Romans.

Objects and uses of both.

The use of mines seems to have originated in the extreme difficulty and labour which were experienced by besiegers, either in battering down the massive walls of a fortress, or in raising their *aggeres* to a level with the towering battlements. It was by stratagem that the assailants first hoped for success, therefore, when they frequently commenced their subterraneous galleries at a prodigious distance in the country, and, passing under the foundations of the rampart, issued unexpectedly to the surface in the heart of the place. But the besieged, as we have seen, soon learned the art of listening to the approach of the enemy's miners, and of defeating his object. They closely watched the point at which he was about to make his narrow issue, and anticipated his assault by throwing in a shower of stones, or other missiles, and combustible preparations, which at once filled up his gallery, while it repulsed or suffocated his miners and troops. But mining was also more actively employed in the defence, and appears to have been rendered altogether available to a greater degree against the besiegers, than by them in assisting the progress of their attack. By driving out subterraneous galleries or countermines from the walls, the garrison not only ascertained the direction in which the enemy's miners were approaching, and intercepted their advance, but were enabled to diverge to those points above which the *aggeres*, battering rams, and towers of the besiegers, were placed, and to effect their destruction. Such was the twofold object in the example to which we have referred, of the system of countermines constructed in preparation for the defence of Gamala by Josephus. When the garrison of a place attacked had driven their galleries under the besiegers' works, they excavated large chambers supported by timbers, filled them with other combustible matter, and set the whole on fire. The effect of the conflagration, by causing the superincumbent mass of earth to fall in, seldom failed both to sink the movable towers and *aggeres*, and to consume all the combustible materials of the various machines and constructions of the assailants: while detachments of the garrison, in readiness for the event, sallied from the gates, and availed themselves of the confusion of the besiegers to assist and complete the work of destruction. But sometimes the design of both parties was mutually anticipated and prevented by the meeting of their artificers in these subterranean labours; as happened at the siege of Syrinx, in Hyrcania, by Antiochus, where the opposing miners encountered each other under ground, and fought with great fury.[*]

Engines of attack and defence.

Of the engines and machines of attack and defence employed in the ancient sieges, the number and variety are too great for detailed description within our limits; and we have already made some mention of them under the head Artillery in our *Miscellaneous Division:* but it will answer every general purpose to mention in this place a few of those most important in their operation, and most common in their use. Nor, as we have already hinted, in our ignorance of many particulars in their form and construction, can more be safely attempted in any modern Treatise, than to notice their purposes and recorded effects. Of projectile engines, the principal were the *catapultæ* and *balistæ:*—terms which have been confused in the application, not less by the ancient Writers themselves than their modern commentators.[†] Upon the whole, it is most probable that the two words were applied with little fastidiousness, and almost indifferently, for the projectile engines of either kind. But, in any case, the question of names is of little moment; since it is certain that, of the two engines, one was used for the projection both of large stones or masses of work, and of darts or even sharpened beams, and the other of the latter missiles only. The one, worked by a cord, being composed in general of one or more wooden limbs, which on release from tension struck with prodigious violence against a capsill, and threw the projectile by the blow; the other, though often of immense size and power, acting upon the common principle of the arbalest or cross-bow. The twisted cords used in both kinds of engine were frequently composed both of the sinews of animals and of woman's hair; and this dry detail of mechanism will recall to the mind of the Classical reader the interesting circumstance of the sacrifice of their tresses, which the heroines of Carthage made to the public defence in the last struggle of their ill-fated Commonwealth. Some of the engines invented by Archimedes for the defence of Syracuse, which deserve notice in this place, varied from these ordinary projectile machines, and consisted in revolving cranes placed on the walls, from whose projecting arms heavy masses of stone and lead were let fall on the galleys of the enemy. Another contrivance of the same master-mind was to employ long levers, having at their outer extremities chains and grappling irons; which, being swung out, caught hold of the men, or even of the vessels themselves; and the latter being drawn partly out of the water by depressing the opposite end of the lever, were suddenly let fall, and either upset or sunk.[*]

Catapultæ and *balistæ*

Power of these machines.

The enormous weight and effect of the masses of rock thrown by the larger engines, and the immense number of these projectile machines which were employed in sieges of importance, are features in the ancient attack and defence of places, to excite our surprise and curiosity. Archimedes, if the relation of the siege of Syracuse may be credited, made them capable of throwing weights of ten talents, or eight hundred pounds.[†] At Ategua,[‡] a shot from a *balista* used by Cæsar's troops, threw down a tower, with five of the garrison and a boy, or slave, who served as a sentinel to give notice of the distending of the machine. Josephus makes repeated mention of a similar power of destruction in the larger engines which were employed in Vespasian's sieges in Judæa. At the siege of Cremona[§] the garrison from their ramparts upset a machine itself upon the assailants below: it crushed every thing beneath it by its vast weight and size, but dragged a part of the wall after it in its fall, and formed a breach for the besiegers. The confined range, however, of these mighty projectile engines, when placed in competition with that of our ordnance, will be heard with a smile by the modern artillerist. The largest used by Titus before Jerusalem could cast a mass of rock only two stadia, or about two hundred yards:[||] though Athenæus speaks of smaller ones which would carry an arrow half a mile. Of the immense number of these engines which were provided in every strong place, there are perpetual proofs. At Marseilles, Cæsar speaks of the *tanta multitudo tormentorum*, with which the arsenal of that city was stored. At the siege of Jotapata, Vespasian had an artillery of one hundred and sixty engines;[¶] at that of Jerusalem, Titus employed three hundred *balistæ* and forty *catapultæ*, the smallest of which could throw a stone of eighty pounds.[**] When Scipio captured New Carthage,[††] he found in the place one hundred and twenty *catapultæ* of the largest size, and two hundred and eighty-one lesser; twenty-three great *balistæ*, and fifty-two small; and an immense quantity of scorpions, or simple cross-bow engines, for the discharge of arrows: and when the Carthaginians before the last Punic War surrendered their arms to the mercy of the Romans, above two thousand engines of all kinds for casting

Immense number used.

---

[*] Polybius, lib. ix.

[†] Folard, who has devoted a chapter (vol. ii. p. 312—323.) to this subject, and insists that the *catapulta* was the machine for throwing stones, is probably, in the strict acceptation, right. His opinion is supported in general by the text of Cæsar, Vegetius, and Ammianus Marcellinus, and by the fair inference of etymological derivation; while the only great ancient authority against him is Vitruvius, an authority still far inferior to Cæsar. In the *Commentaries (De Bello Civili*, lib. ii. at the opening) it is said, that the Marseillois shot spear-pointed beams twelve feet long from their largest *balistæ—maximis balistis missi;* and, further on, more expressly, that stones were thrown from the *catapultæ,—saxa ex catapultis lateritium discuterent.* Vegetius (lib. iv c. 21.) distinguishes the *balista* as throwing darts, and the *onager*, or wild ass, (a name which appears to have superseded that of *catapulta* for the same engine,) as casting stones. *Balista spicula emittit, onager dirigit lapides.* The Greek derivation of both terms should seem to settle the question. *Balista*, from Βάλλω, *jaculor*, certainly describes the point-blank shot of the dart or *jaculum; catapulta* from κατὰ, *circa, et* πάλλω, *vibro*, the swinging hurl of the stone. The former might discharge its missile through an embrasure, like the modern cannon; the latter could be used only with a vertical range over a parapet, like our mortars. Yet, on the other hand, Vitruvius (lib. x.) pointedly reverses the terms of the two engines; and it must be confessed, that Hirtius, the continuator of Cæsar, (*De Bello Hispan.*) distinctly calls an engine, which destroyed a tower by the discharge of a mass of rock, a *balista.* This, and the vague disagreement of ancient Writers, may beget a strong suspicion that the words were often used indifferently for either projectile engine.

stones and darts, were delivered up from the arsenals of the city.

Aries, or battering ram.

Ram-tortoise.

The common purpose of all these engines in attack was to destroy the tops of the parapets, to kill and wound the men behind them, and generally to ruin the defences of the place, and by rendering them untenable to drive from the ramparts the troops of the garrison, whose missiles would otherwise annoy the workmen, and impede the progress of the approaches. To form a breach in the body of the rampart, through which the assailants might enter by storm, was left to the operation of another well-known engine of prodigious power:—the *aries*, or battering-ram. This was a huge beam, pointed horizontally, with a head of brass or iron: sometimes shaped like that of the animal from whose manner of striking it derived its name. In the rudest form of the invention,* it was probably only a transverse beam, balanced from a mast which was set up before the ramparts, and swung against them with its point forward by a number of men, until its repeated blows shook and brought down the wall. But, at least as early as the Age immediately preceding that of Alexander,† contrivances were adopted for enclosing the ram in a movable shed, and thus advancing it to the walls under cover. The whole engine so composed acquired the name of the *ram-tortoise*, which Vegetius derives from its resemblance "to a tortoise with its head poked out of its shell." The shed was usually constructed, like all the movable galleries and towers of attack, of timber covered with the hides of bullocks and other animals: it moved upon wheels or trucks, and had often upper stories for missile machines. In this shed, the ram itself was sometimes worked to and fro, upon a number of trucks in a groove, to give its blows; but it was more frequently suspended by ropes or chains from the roof, and its head thus violently swung against the wall with repeated concussions, until it beat down the mass of the rampart.

Helepoles, or movable towers.

Their stupendous height and dimensions.

Of the great movable towers, or *helepoles*, in common use at sieges from the Age of Alexander, the accounts transmitted to us are, unlike those of many other machines, perfectly intelligible. But the stupendous height which was given to them, the immense labour and quantity of materials required for their construction, and the difficulty of moving forward such towering and unwieldy masses, are among the most extraordinary circumstances of ancient warfare, and would be absolutely incredible, if their constant use and proportions were not too well authenticated for doubt. They were generally of ten stories or more, and above a hundred feet high; and Vitruvius,‡ on the authority of Diades, a famous engineer in Alexander's wars, recommends that the breadth of their base should be from seventeen to twenty-three cubits, and their height from sixty to one hundred and twenty cubits, and that every tower should be gradually narrowed at the top to four-fifths of its base. The *helepolis* moved upon four, six, or eight broad oaken trucks, and it was composed of timber,§ covered with raw hides, as we have already observed, to protect it from fire. The uses of those towers were obvious: whether placed on the natural plain or on the *agger*, to gain the advantage of height, and overlook the walls; to drive the enemy from their defences by showers of missiles from the machines in the different stages and on the summit; and, finally, when the tower had been rolled close to the rampart, either to enable the ram to work against it from the lowest floor, or to afford a passage for the assailants to the wall from the top, by means of a drawbridge, prepared for that purpose, and let down upon the battlements of the place.

Various smaller engines.

Of the smaller movable sheds of attack, since they were constructed much on the same principle, we have neither space nor occasion to give any lengthened description. Such were the *pluteus*, the *musculus*, the *testudo* of approach, all covered buildings of carpentry, hides, hurdles, &c. pushed forward on trucks, for levelling the ground in front of the heavier *helepoles* and ram-tortoises, for covering the various works of approach, for filling up the moat of the place, and for undermining the walls. Neither is it necessary to load our pages with an account of the various machines for escalade, cranes for raising the assailants to the battlements, (especially from the galleys in maritime sieges,) and the thousand other expedients which the martial ingenuity of the Ancients dictated under as many varying circumstances; and which are to be found in all the old professional Treatises.

General course of attack,

From the particulars into which we have already entered respecting the machines and constructions employed in the Grecian and Roman practice, the general reader will already have acquired a sufficient insight into the scientific process of an ancient siege. He will have observed that the primary object of the besieger was to approach the walls of the place under cover, and with the least possible sacrifice of life to his troops. With this view were employed either: 1st, subterranean galleries to arrive at the foundations of the ramparts; 2dly, covered galleries and communications of approach, such as *vineæ* whether raised blinds or trenches, and movable sheds, and towers; 3dly, *aggeres*, or mounds rising to the height of the battlements, and pushed to the edge of the ditch, or even filling it; 4thly, missile engines of all kinds to ruin the defences, to overpower the discharges of the garrison, and to drive them from the ramparts. This primary object of touching the walls having been effected, the ultimate process was either to bring down the rampart, and form a breach for passing into the place, by the mine or by the strokes of the battering ram; or else to pass over it by drawbridges from the *helepoles* and *aggeres*, and pour columns of troops into the place.

and of defence.

On the other hand, it was the object of the besieged to impede the progress of the enemy by destroying or rendering useless their works, and overpowering their workmen with missiles. For this end, they employed the greatest possible number of projectile engines on their towers and walls, and kept up an incessant discharge upon the approaches; they hurled down all kinds of heavy masses from the walls to crush the sheds of the assailants below; they attempted frequent sallies to fire the towers, sheds, *vineæ*, engines, and *aggeres*, for which the combustible nature of the timber and faggots, and other materials which were necessarily used, both in the wooden buildings and accumulated mounds of the besiegers, gave great facility; and the labour of weeks and months was thus frequently destroyed in as many hours. On their walls, the garrison protected themselves from the missiles of the assailant, by the same contrivances of wooden blinds, hurdles, hides, &c., which he used. To the successful employment of countermines for sinking *aggeres* and overturning the *helepoles* we have already adverted: but there were sometimes even simpler modes of arresting the approach of those unwieldy masses of timber, of which a single example, related by Vitruvius,* may suffice. At the siege of Rhodes, Demetrius, one of the most able of the martial successors of Alexander, who had acquired the surname of Poliorcetes, (besieger of cities,) from the number and success of his enterprises, constructed an enormous *helepolis*, one hundred and twenty-five feet high and sixty broad, and so secured with hair-cloth and raw hides, that it could stand the blow of a stone weighing three hundred and sixty pounds from an engine, and was probably indestructible by fire. This huge tower itself is said to have weighed three hundred and sixty thousand pounds; and its approach threatened imminent peril to the besieged. Yet merely by inundating in the night the soil over which it was to pass with quantities of water, mud, and filth, the citizens produced such a quagmire, that the dreaded machine stuck fast and sank by its own weight, so that it could be moved neither forward nor backward; and Demetrius was compelled there to abandon it, and to raise the siege! The most formidable engine, when its advance to the walls was once effected, seems to have been the ram: yet the besieged were not without the expedient of strengthening their rampart against its shocks, to an immense mass and thickness at the points most exposed to attack; and sometimes mattresses of wool and hair-cloths were hung over the walls to deaden the blows of this battering machine. Another frequent contrivance was to noose the ram by a chain or cord dropped from a crane upon the rampart, and by this means to raise the head of the beam in the air, while fire, the great auxiliary of the defence, was showered in every form upon the tower or shed.

---

* Vitruvius, lib. x. c. 19.

† *Idem.*

‡ *Ubi suprà.*

§ Cæsar's tower of brick at the siege of Marseilles is a famous example of another kind. But though constructed under the range of the missiles of the garrison, it was rather a lofty redoubt for defence against sallies than a tower of attack, and was, of course, not movable.

Superiority of the ancient Art of Defence to that of Attack.

Altogether, therefore, as will be concluded, the Art of Defence in Ancient Fortification had an infinite advantage over that of Attack; and it was only by immense numerical superiority and mechanical means, by unwearied labour, and indefatigable patience and activity, that the assailant, advancing on his feeble lines and heads of attack, could approach the defences, and effect a passage through the ramparts of a well-fortified place. For once in the History of mankind the Art of fortifying had nearly perfected its professed object; and apart from the ravages of famine and pestilence, and the bane of domestic treason and dissension, every strong place, if well-garrisoned, and defended with as much skill and courage as it was assailed, may almost be pronounced to have been impregnable. Nor were there wanting, in the ferocious principles of ancient warfare, strong motives of human passion to increase the moral energies of a besieged population. While, from behind their lofty and solid ramparts, with plenteous stores of provision and a well-filled arsenal, a brave and united people might securely defy the assaults of a besieger, the dreadful consequences of surrender or defeat were far more appalling than the ordinary privations of a siege. For the best fate they might expect from the mercy of the conqueror was slavery in its bitterest forms: the sure consequences of capture by assault were death by the sword to themselves, and worse than that death to their women and children. In our ordinary modern warfare, in which a garrison may safely resist behind their last intrenchment with the certain power of an honourable capitulation, it is impossible for us to conceive the agony of patriotism and desperation, by which the defenders of an ancient city were wrought to superhuman endurance. The whole siege was in truth a death-struggle of ferocity and terror, not a mere effort of martial emulation. Even the horrors of a modern assault in their rare and unmitigated excess, fall more cruelly upon the often neutral and passive inhabitants of a city than upon the troops of the garrison, to whom quarter is seldom denied. The modern soldier resists or surrenders, with equal indifference to the lot of a population to whom he is bound by no ties of affection: but the ancient warrior beheld all that was dearer than life involved in his own ruin; and in anticipation of the sanguinary and brutal triumph of the victor, might well shudder, not at the death which he probably welcomed, but for the slaughter, the violation, and the servitude, which his own fall would prepare for his miserable kindred.

Aided by the despair of the besieged.

Consequences of defeat or surrender.

CHAPTER II.

Fortifications of the Middle Ages.

Long continuance of the ancient mode of fortifying.

We have abundant evidence from the Histories of the Sieges which have taken place in Europe and Asia, that the nature of the military engines used in the attack and defence of fortresses underwent no material change, from the days of Cæsar till the discovery of gunpowder; and it is known that the ancient *balistæ*, *catapultæ*, &c. continued to be employed in conjunction with cannon for a considerable time after the latter were mounted on ramparts or brought into the field. We may, therefore, reasonably conclude that, during all this long period, the manner of fortifying towns and military positions remained the same as that described in the Works of Vitruvius, who is believed to have lived in the time either of Augustus or of Vespasian: but the employment of the modern artillery, small indeed at first, and far less important in its effects than that which is used at the present day, at length rendered it necessary to exchange the lofty stone walls of the Ancients for ramparts of earth, which were soon found more efficacious in resisting the shock of this powerful arm.

Earthen ramparts, why not sooner employed.

It may, at first sight, seem remarkable that such ramparts were not frequently constructed even while the ancient engines were in use: since it is evident that the material which is best capable of resisting the momentum of an iron ball, must also have been best capable of resisting that of a battering-ram; and it would seem to have been impossible, supposing the parapet formed as at present, with its exterior face at an angle of forty-five degrees with the horizon, to bring such machines as the *helepoles* near enough to permit the assailants to pass into the fortress by a bridge, thrown upon the parapet from the top of the machine. Ramparts constructed merely of earth are certainly mentioned by the Ancient Writers as the fortifications of towns and military posts: but, except where they served as lines to protect a country from the inroads of Barbarians,—like the walls of Hadrian and Antoninus in Britain, and the chain of redoubts constructed along the Illyrian frontier in the latter Ages of the Roman Empire,—such appear to have existed only among rude nations and in situations of small importance. That elevations of earth were sometimes formed for the protection of the ordinary brick or stone ramparts is, however, rendered probable by the fact, that there remained, in the XVIth Century, in the ditches of some ancient fortresses, a bank of earth parallel to the sides of the fosse, but separated from both, and covering the inner wall of the excavation as far up as about three-quarters of its height. It is asserted by Maggi,* that such banks in his time existed in front of the old circuit of wall at Calais, and at another place in Flanders; and he adds, that at Pisa, banks of the same nature were placed close against the walls of the curtains for the purpose, he supposes, of resisting the engines brought against them by the besiegers.

---

* Lib. x. c. 22.

Facilities afforded by such works to escalade.

But in ancient warfare the practice of engaging in combat hand to hand was so general, and personal prowess and self-devotion were held in such estimation, that when an attack by storm was possible, it was always preferred to a slower but more secure process: the sacrifice of life entailed by an open assault being then less regarded, than that of the time which would be incurred by forming a regular siege. It being such assaults, therefore, that the defenders would chiefly apprehend, it may be conceived that ramparts similar to those of modern construction would be thought to offer too many facilities to an escalade; and this, together with the opinion that they would be more easily undermined, may account for the preference given to ramparts of stone or brick. While, therefore, the penetration of the rampart at its foot was to be feared, thick stone walls remained necessary: in order that a sufficient resistance might be opposed to the enemy's miners. And, while the walls were liable to be passed by escalade, it was essential that they should be lofty, in order to augment the difficulty of the assault. In fact, the heights of the walls and of the opposing turrets of the besiegers seem, in emulation of each other, to have gone on increasing during all the time that the old system of attack and defence continued: but a great thickness of wall was only required near the foot; and this was accomplished by raising a mass of earth there, either on the interior or exterior. In the parts of the wall above the place where the ram might come in contact with it, it was sufficient to have the thickness adequate to resist the stones or other missiles thrown from the machines: consequently, the loop-holed galleries therein made, to serve for communications and as stations for the archers, became admissible, and did not diminish too much the strength of the rampart.

Proofs of the unvaried character of the Art of Fortification in the Classical and Middle Ages.

A. D. 323.

To mention only a few circumstances in support of what has been asserted concerning the unvaried character of the Art of Fortification during the period above-mentioned, we may observe that, in the IId Century of our Era, the City of Byzantium, which was then considered impregnable, and which, during three years, resisted all the power of Severus, and all the means employed in the ancient mode of attack, was fortified, as were all other Cities of the preceding Ages, with walls and towers of masonry.† In the same style also, after their subsequent destruction, those walls were rebuilt; and when besieged by Constantine, the attack and defence are described as being conducted in the accustomed manner. The assailants raised an *agger* or mound, of equal height with the walls of the place; surmounted this huge elevation with lofty *helepoles* and projectile engines; and finally breached the walls by the ram.* So also, when the City became the seat of the Eastern Empire, the new fortifications were of the same kind as the former: the extent of the walls and the number only of towers being augmented.† Of the latter, it is said, that, in the reign of Theodosius, fifty-eight were overthrown by an earthquake, and subsequently restored.‡

Evidence of Procopius.

We may collect from the Works of Procopius§ that the military architecture of the VIth Century differed in no respect from that of preceding Ages: for, in describing the fortifications constructed about Dara in Mesopotamia, during the reign of Justinian, that Writer states that the City was surrounded, at the distance of fifty paces from each other, by two walls, which were strengthened by towers: that the inner wall was sixty feet high, and the towers one hundred feet; and that besides the platforms at the top of the walls and towers, on which the defenders were to be stationed, there were galleries formed in the thickness of the former. He observes that the exterior wall was less lofty; and that against the back of the towers were raised large elevations of earth to serve as places of arms for the defenders at the time of an assault. The whole was surrounded by a double ditch; and the entrance was protected by an outwork of a semicircular form.||

State of the Art between the IXth and XIIth Centuries.

If we pass over the dark interval between the IXth and XIIth Centuries, we shall find that, at the latter epoch, the fortifications of Cities had been maintained in all their former strength; but that no improvement had been made in the nature or dispositions of the works, nor in the modes of attack and defence. On the contrary, it may be gathered, from the relation of the sieges undertaken in the First Crusade, that the state of martial Science, in this as in all its other branches, had retrograded since the Ages of Classical Antiquity. Thus, as we have seen, in another portion of our Work,¶ Nice, when invested by the Crusaders, was surrounded by double walls of stupendous height and thickness, provided with a deep ditch, and flanked at intervals by no fewer than 370 towers. The attack of the City was carried on by means of lofty wooden towers, the *helepoles* of the Ancients, now termed *belfredi*, or *belfrois*;** by covered galleries and movable sheds, the *pluteus*, *musculus*, &c. of old, now called indifferently foxes and cats, or *chat-chateils* when surmounted by a tower; by battering rams contained within all these structures; and, lastly, by all the balistic engines of earlier Ages. But the whole of the towers and galleries of attack were burned by the Greek fire of the besieged; and it was not until after much mismanagement and loss, that the Crusaders, by the aid of an Italian engineer, succeeded in attaching a *chat-chateil* to the walls of the City. From that machine, undermining the foundations of a tower, which had been injured in a former siege and leaned forward from its base, while they supported the superincumbent mass on strong wooden props, they finally, by firing these timbers, brought down the whole structure

Sieges in the Ist Crusade.

at a single crash, and displayed a yawning breach. Two years afterwards, Jerusalem was besieged and defended in a similar manner: after the destruction of various other engines of assault by fire, the besiegers could advance only one movable tower to the walls at a point at which the fortifications were low and the ditch deep. The latter was filled up; a *barbacan* or outwork was beaten down; the tower was rolled up to the inner wall; its drawbridge was let down upon the rampart; and the troops rushing over the battlements obtained possession of the City.*

Examples of the unchanged state of the Art in the Italian wars of the XIIth and XIIIth Centuries.

The Histories of the wars in Italy, and particularly the relations which have been transmitted to us of the sieges of Como, Tortona, and Cremona, show that the towns in that part of Europe, during the XIIth and XIIIth Centuries, were fortified and attacked in the ancient manner. The first of these places seems to have been strengthened by castles in the nature of advanced works: for the Milanese, who besieged it, are said to have passed them without attack; and encamping under the walls of the city, they caused to be erected four great towers covered with hides, which were wheeled up to the walls. From these the cross-bow men, stationed on their tops, annoyed the defenders; and between them were placed what are called *gatti*, or cats: a sort of battering ram having at the end an iron hook to tear out the stones which were loosened by the shock. *Balistæ* also were used for throwing pieces of rock against the walls.† In a manner precisely similar were the two other places above mentioned attacked by Frederic Barbarossa; nor do we find any other difference, except such as arose from local circumstances, in the nature of the attack on Constantinople when it was taken by the Latins in the IVth Crusade. It is stated that the towers of the City on the land side were raised above their ordinary height by several stages of wooden turrets, in order to command the machines of the enemy; and that the Venetians having disposed their fleet along the wall, on the side next to the port, swept that wall with arrows and stones discharged by men stationed on the masts of the ships. This division of the army on landing is said to have taken as many as twenty-five towers;‡ a proof of their vicinity to each other, and that they did not exceed the usual size of such works.

And in the siege of Constantinople.

A. D. 1203.

Influence of the Feudal System upon the construction of fortresses.

The rise of the Feudal System, however, during the Dark Ages had produced a description of fortress in the Western Kingdoms of Europe, which, while constructed with embattled walls and towers according to the ancient system, exhibited several new and peculiar features. These were suggested by the nature of the site, and the purposes which distinguished such strong-holds from large and populous cities. The anarchical state of Society, and the frequency of private wars among the Feudal Nobility, bestowed a license and imposed a necessity upon every Chieftain to fortify his house. While the dwelling itself of the lord and his family was strongly constructed in the form of a tower, and rendered capable of defence by a small body of domestic retainers, against any sudden attack, a larger space, sufficient for the refuge of his numerous vassals with their effects, and for the endurance of a regular siege, was obtained by surrounding the main building with a single or even double circuit of walls. The rural fortresses which, as we are informed by Procopius, were plentifully provided in the frontier Provinces of the Eastern Empire under the reign of Justinian, afford an earlier example of the same kind of works: since they consisted of a stone or brick tower, in the midst of an area surrounded by a wall and ditch, to which the neighbouring peasantry might retire with their cattle for protection against the inroads of the Barbarians. But the castles of the Feudal Nobility throughout the Dark Ages were continually enlarged in extent and increased in strength, until they were made capable of containing powerful garrisons, and rendered almost impregnable against the ordinary modes of assault.

Description of a Feudal Castle.

Although the license of private war was more severely restrained in England than in the Continental States of Europe, a very complete idea may be formed of the castles erected by the Feudal Nobility from the existing remains of such structures in our own Country. These show that the residence of the proprietor was a large building, generally rectangular, of great height, and strengthened at the angles by turrets, in one or more of which were the winding steps leading to the several floors, of which there were sometimes four or five, and to the upper platform of the edifice. Underneath were dungeons in which the captives taken in the field, and often the victims of lawless power, were confined; and frequently subterranean galleries, commencing under this building, were carried far beyond the outer walls, to facilitate escape in the event of the castle being taken. Near this edifice were commonly situated the chapel, stables, and the domestic offices; the whole were surrounded by embattled walls which were sometimes double; and the name of the inner and outer *ballium* was given to the areas which those walls respectively enclosed. The periphery of the walls was generally irregular and adapted to the nature of the ground; at intervals were placed towers of a square or circular form as in other ancient fortifications; and these, though used for the purposes of defence, served also as magazines, or dwelling-houses for the principal officers belonging to the castle.

When the walls crowned the summit of a rock, no ditch was necessary, but when the surrounding ground permitted the works to be accessible, the whole was surrounded by a broad and deep *fosse*. The grand entrance was flanked by embattled towers, closed by massive gates, and protected by machicolations and a *portcullis* or close grating of iron, which was drawn up and let down by grooves prepared in the stone work. The ditch was crossed by a drawbridge, which, in time of danger, was raised, to prevent any one from entering within the walls; and the bridge was frequently covered by an exterior work, called a *barbacan*, consisting generally of a stone wall built in the form of a portion of a circle, or polygon, strengthened at intervals by towers and protected by its own ditch and drawbridge. Within the outer wall there has been frequently observed a mound of earth, and this is supposed to have been a sort of *cavalier* (as such raised batteries are called in modern fortification), on which engines were placed to oppose those of the enemy. The central building generally served as a *keep*, or citadel, which might hold out for some time after the walls of the castle were taken; but when some great elevation of the ground rendered the spot difficult of access, the keep was formed on the periphery of the inner or outer wall. The ascent to it from the *ballium* was by narrow steps; and deep wells were dug within to supply the garrison with water.[*]

Mode of besieging such fortresses.

In the siege of such fortresses, since the range of the warlike machines then in use was not great, the assailants sometimes began their operations with the attack of the outer wall, which frequently consisted only of a row of strong palisades, and was then denominated the *lists*. Many feats of Chivalry were here performed by the Knights and men at arms, who considered the assault of that work as particularly belonging to them; the weight of their armour preventing them from scaling the walls. The besiegers having carried the lists, brought up their machines, and established themselves on the outer edge of the ditch, which, under cover of their tortoises, they began to fill with *fascines* or faggots: over this surface were impelled the movable towers, from which the cross-bowmen annoyed the defenders; darts and stones were thrown from the engines; and the walls were either battered by the ram or undermined. The smallness of the range of missiles from the ancient engines rendered it no disadvantage to the works to be commanded at the distance of four or five hundred yards; and such was actually the case with the Castle of Dover, which was once considered as the key of the Kingdom.[†] Fortifications of the kind which we have been describing yet remain in different parts of the Continent of Europe, situated on rugged and often inaccessible rocks, showing their ruined battlements and towers from a great distance; and recalling to the mind of the traveller those tales of chivalric exploits, of which the relation has so often charmed his youth.

Invention of gunpowder.

Slow progress of the changes which it produced in the Science of Fortification.

Example in the last siege of Constantinople. A. D. 1453.

It must have been in the wars which devastated the North of Italy in the beginning of the XIVth Century, and probably between the death of the Emperor Henry VII. and the election of Louis of Bavaria, that the invention of gunpowder, which was subsequently to produce so great a change in military operations, took place. But whatever may be the precise date of its discovery, it appears to have been first used in the field by the Venetians, in A. D. 1330. Before the XIth Century the Italians, from their frequent intestine wars, had made themselves skilful in the art of attacking and defending places; and Pisan and Genoese engineers seem to have had the direction of all the sieges carried on by the Crusaders against the cities of the East. We find them also employed in the erection of fortresses in Flanders so late as the time of Charles V. It is not, therefore, wonderful that a people thus exercised in martial science and practice should have been the first to adopt an invention, which promised to render victory an attendant on every movement of their armies.' But the discovery of gunpowder does not seem to have produced at once the change that might have been expected in the construction of fortresses; nor to have given complete success on every occasion of its employment in the attack of those already existing. In fact, however, the first guns, except in a few cases, were so little superior in effect to the rams and *balistæ* of the Ancients, that the latter were long used in conjunction with them for every military purpose to which either was applicable. The most remarkable instance of such an admixture occurs in that fatally memorable siege which, in A. D. 1453, gave the last City of the Romans to the power of a Turkish Sultan. The fortifications on the land side of Constantinople consisted of a double wall, with a ditch in front one hundred feet deep, and extending to the length of four miles. Against this wall and its towers, were raised fourteen batteries of guns, among which were three pieces said to be capable of throwing stones weighing from six hundred to twelve hundred pounds. But, with these, we read that there were engines for throwing darts, and rams for battering the walls: as if the effect produced by the guns was not sufficiently great; or as if the breaches which they made were too steep to be ascended. The ditch being at length filled, a movable turret was advanced on rollers up to the wall, where, however, it was destroyed by the fires of the besieged. The guns of the Greeks are said to have been of small calibre, the weakness or want of breadth of the ramparts not permitting a heavy artillery to be used upon them.[*]

This, however, is not the earliest instance in which the ancient and modern artillery were combined: for when, in A. D. 1383, the Bishop of Norwich besieged Ypres, the garrison is said, by Walsingham, to have defended itself so well with stones, arrows, lances, Greek fire, and guns, that they obliged the English to raise the siege, and leave behind them all their artillery.[†]

CHAPTER III.

Rise of the Bastion System.

The transition to a new style of fortifying almost imperceptible.

In almost every Science and Art the progress of improvement has been so gradual, that the difference between two consecutive states has, for the most part, been too small, to admit precise observation of the epoch at which any particular improvement took place. It ought not, therefore, to be a matter of surprise that, in Military History, no trace should be found of the transition from the ancient walls and towers, to that form and disposition of the works which the use of artillery rendered necessary. But the absence of all notice of any novelty in Fortification between the Greek or Roman style and that which is known to have been followed in the XVIth Century, may, perhaps, be considered in itself as a proof that the works of that Age were those which immediately succeeded the constructions belonging to the Ancient School. It is more than probable, indeed, that, for many years after the invention of gunpowder, no entirely new fortifications were erected, but that, on the accessible fronts of towns, the thickness of the ancient ramparts was increased, in order that they might be better able to resist the shock of a more powerful artillery. At the same time the great height of the walls, which until then had constituted their principal advantage, became a serious defect: for being thus exposed to the view of the enemy, they were breached after a few hours' firing from guns planted even at a considerable distance from the works. It was, therefore, soon found necessary to lower the walls and cover them by parapets of earth constructed in front; and in order to secure them against the attempts of the enemy to carry them by escalade, the depth of the ditch was proportionally augmented: but with these exceptions, the other parts of the same fortress remained unchanged. From the description given of the siege of Metz, in A. D. 1552, it appears that the fortifications of that city then consisted of a single wall with square and round towers; and that to put it in a state of defence, the Duc de Guise, who commanded, raised cavaliers, or mounds of earth on the exterior for cannon, with parapets formed of large gabions: he also thickened the walls inwardly by the same means, and within their periphery he formed retrenchments of earth strong enough to resist the guns of the enemy, who had breached the exterior wall in several places.

---

[*] Grose, *Milit. Antiq.* vol. ii. p. 336, 337, &c.

[†] Grose, *ubi suprà.*

[*] See Gibbon, *Decline and Fall, &c.* c. lxviii: who in that splendid narration of the capture of Constantinople by the Turks, has not failed, with his usual acuteness, to remark the admixture of the ancient and modern artillery and expedients of attack as a distinguishing feature in that memorable siege.

[†] Walsingham p. 303, 304.

Construction of angular and flanking towers, or balvardi.

The destruction of the machicolated parapets by the guns of the besiegers at an early period of the siege, by depriving the defenders of the cover behind which they used to annoy the enemy when he was at the foot of the wall, evidently rendered it necessary that the faces of the towers should be seen and defended by fires directed from some other part of the works; and, for this purpose, the engineers of the day replaced the old round towers by others with plane faces, presenting an angle to the front. It is alleged, indeed, that a construction of this kind had been occasionally employed by the Ancients; and that some of the towers of Jerusalem, as well as many of those about the castles of the Nobility of a former Age, were of an octangular form on the plan.[*] But, let this have been as it may, the necessity for such flanking towers now became evident; and from within half a Century, probably, after the first introduction of cannon in the field, we may date the general practice of constructing such works at the angles of the polygonal wall surrounding a fortified place. A tower consisting frequently of two faces forming a salient angle, and of two flanks, but sometimes having a greater number of faces, and situated as we have described, but of dimensions hardly exceeding those of the Roman times, was called *balvardo:* a name derived by Maggi[†] from *bellunguardo*, signifying that which constitutes the strength or maintenance of battle. It is observed also by the same Writer, that, from the acute angle formed by the two faces, the towers had the name of *puntoni*, (probably from their resemblance to the pointed head of a spear or other weapon,) and he adds, from the information of Marco Manini, whom he qualifies with the character of a diligent observer of the things of his time, that they had been so called for seventy years before; which, as his Work was written in A. D. 1584, carries the invention of this species of tower so far back, at least, as the commencement of the XVIth Century.[‡]

Provisions for their defence from the curtain or connecting line of wall.

The same writer alleges, that the curtain or connecting line of wall between the towers, was at first made straight, and served for the defence of the *balvardi* or *puntoni*, in which, he observes, consists the safety of the city: but he goes on to say that, since nothing can be made by Art which by Art may not be destroyed, the *shoulders* of the fortress, as he calls those works, were ruined by the besiegers, and then the curtain was exposed. To remedy this evil, he recommends that the latter should be broken in two parts, forming with each other a reentering angle; and in this way, he observes, the City of Nicosia in Cyprus was, in his time, fortified with eleven *balvardi*, by Giulio Savorgnano. He admits, moreover, that this method of breaking the curtain was not new, but the invention of a preceding Age, and asserts that, in the year 1550, he saw such a curtain in the fortifications of Padua. It is, also, worthy of remark, that Maggi, in describing the advantages of the broken curtain, states that when the enemy would attempt to breach it by a direct fire, he must present an end of his battery to one of the oblique lines of the curtain; from which that battery may consequently be enfiladed. In the plans of fortresses proposed by this Writer, the faces of the *balvardi* are equal to about one-seventh only of the distance between two of those works; the lengths of the flanks are little more than one-twentieth of that distance: and half the flank is taken up with an *orillon*,[*] evidently intended to cover that part of the work from the view of the enemy: two tiers of guns are placed on the flanks, to fire either over the rampart, or through it from casemates, for the defence of the ditch.

Probable Authors and Era of their improvements.

Tartaglia of Brescia, and San Micheli of Verona, who lived only a few years earlier, and were even for some time contemporaries of Maggi, are mentioned as engineers distinguished for the improvements which they introduced in the Military Art. To the former is ascribed the first formation of the *orlo*, or covert-way, surrounding the fortress on the exterior of the ditch, a work the importance of which has been ever since acknowledged; and to the latter, the invention of the *balvardo* itself. This opinion is, however, founded only on a passage in the *Vitæ excellentium Architectorum* of Vasari, which was published at Florence in A. D. 1597, where it is said that, before the time of San Micheli, the *balvardi* were made circular; and Maffei, who, in his *Verona illustrata*, advances that opinion, observes that there are still among the works surrounding that city some towers on which are inscribed the dates A. D. 1523 and 1529, at which times San Micheli is known to have been employed by the Venetian Government in the construction or repair of several fortifications in Italy and the Greek Islands.[†] But this only shows the probability that such works were then constructed by San Micheli, not that he was the first to construct them. Tartaglia makes mention of *balvardi*, in his *Quesiti ed Inventione diverse*, published at Venice A. D. 1546, as a new invention of great importance. Brantome and Montluc attribute the invention to Antonio Colonna, who was killed at the siege of the castle of Milan. The honour of the invention is even assigned to the Ottoman Commander, Achmet Bassa; who, it is alleged, raised such at Otranto when, A. D. 1480, he made himself master of that City. But it has never been the character of the Turks to make discoveries in Art; and it is more probable that Achmet only caused his engineers to copy the forms of works which might then have been recently introduced.

Numerous fortresses constructed by the Venetians in the XVth and XVIth Centuries.

In fact, after the taking of Constantinople, while the wars in Italy rendered additional works necessary in that Country, the apprehension that the Turkish power might still further extend into Europe, induced the Venetians to rebuild and increase the number of their fortresses in Corfu, Candia, and Cyprus. A time of great political excitement, like that of which we are speaking, by calling into action the powers of the human mind, is favourable for the introduction of novelties; and, to the improvements which then took place in the Sciences and Literature, must be added those made in the Art of Defence, which the new constructions would afford an opportunity to put into execution.

---

[*] It may also be observed that some of the ancient towers of Carisbrooke Castle have the appearance of square buildings placed diagonally with respect to the walls between them.

[‡] *Ibid.* cap. 10.

[*] An *orillon*, or *orillion*, (*Italicè orecchione*,) so called from its resemblance to an *ear*, is a prolongation of the face of a *balvardo* or bastion in a semicircular or rectangular shape, beyond the flank, which it thus covers in a retired position from the view of the enemy.

[†] The bastion *Delle Maddalene* at Verona, which, though small, exactly resembles one of those constructed by Vauban, bears date A. D. 1257

Celebrated engineers of those Ages.

To the engineers whom we have above mentioned as living about the time of the great change in the construction of fortifications, we may add, Cataneo, San Marino, and Albert Durer, who were nearly contemporary with each other. No particular systems of works indeed are ascribed to them: but they wrote on the principles of the Art as it existed in their day; and we seem to be indebted to them for the first application of almost every work raised for the defence of a modern fortress. Since those days the most distinguished engineers have been Errard de Bar le Duc, (A. D. 1594,) Marchi, (A. D. 1599,) De Ville, (A. D. 1639,) Pagan; (A. D. 1645;) and in later times, Vauban, Cochorn, and Cormontaingne.

Invention of bastions and ravelins.

The necessity of covering the curtains of masonry which joined the ancient towers, to prevent them from being destroyed by artillery, suggested, soon after the invention of the *balvardo*, the construction of works in earth in front of those curtains. These, which were made like the former, with two faces forming a salient angle, and sometimes with flanks, were well known in the time of Errard* and De Ville; and the invention of them is by the latter ascribed to the Italians.† But it appears that they were first used in that situation subsequently to the time of Castriotto and Maggi, or between the years 1584 and 1594: since the last of these Authors makes no other mention of them than that the bastion of Gatti at Padua, which he designates as a *rivellino*, or ravelin, was a work of that nature.‡ It should seem that, at first, all works of earth, whether constituting part of the fortifications of a town, or of the retrenchments made during the siege, were, in the time of Maggi, denominated *bastioni;* (great buildings;§) and probably it was not till some time after the system of the Italian engineers was adopted by those of France, that the name of bastion was restricted to the work which had been made to replace the *balvardo* at the angles of the polygon surrounding the place fortified. It may be observed, that Maggi never uses the term *bastioni* except when speaking of works made with earth; and that these were sometimes constructed without due care, is proved by a passage in his third book, where it is said that Lucca Martini had built one at Pisa which, for want of bond timbers, gave way on one side from the effects of rain; and that a like accident befell a work constructed with earth at Corfu, by San Micheli. The *rivellino*, or ravelin, whose name is apparently derived from *velletta*, or *vedella*, a watchman or sentinel, was at first constructed beyond the circuit of the walls; and Errard, in some places, uses indifferently the word bastion and ravelin to designate a work so situated.

Other new constructions of the same epoch.

Platforms.

Cavaliers.

The advantage of having capacious works may be said to have been felt almost as soon as the new method of fortifying was introduced; since Maggi complains that the fortresses of his day could not be defended after a breach had been made in the walls; and assigns as a reason the smallness of the places, which would permit no retrenchments to be made in them. He observes, also, that it would be better to lay out money in making the *balvardi* large, the walls high, and the ditches deep, rather than in multiplying the number of the *balvardi:* for if these are too near each other, the defenders are liable to receive injury when the artillery on the walls is fired against the works of the enemy. To increase the defence of fortresses, he says, engineers had invented platforms, cavaliers, and casemates. The first he describes as of two kinds: either small works, resembling the modern bastions, but projecting from the middle of the curtain, and containing on their flanks artillery to defend the faces of the *balvardi* when these were not very distant; or retired spaces in the curtain resembling the second flanks, as they are now called, in Vauban's Third System, and on which, also, artillery was placed for the same purpose. The cavaliers were elevations of earth either on the middle of the curtain or at the back of the *balvardi;* and on these, also, artillery was placed, under cover of *gabions*, or cylindrical baskets of earth, for the purpose of keeping the enemy at a distance by the superiority of their command.

Casemates.

Orillons.

Counter-arches and galleries.

Lastly, the casemates were recesses in the flanks of the *balvardi;* and, according to Castriotto,* they were sometimes made, in the form of vaulted galleries, across the ditch; but he recommends that they should be built behind the outer edge of the ditch opposite the faces of the *balvardo*, and on each side of its salient angle, their use being, as at present, to defend the ditch when the enemy had entered it. The Italian engineer admits that, if cannon were fired from them, they might become unserviceable on account of the smoke; but he proposes to employ in them only cross-bows and engines for stones; and he alleges that they may be useful for galleries of countermines. The *balvardi* of that day were always made with very short flanks, which were divided into upper and lower stages, each containing only one or two guns, and protected by *orecchioni* or *orillons*, which were generally of a circular form, at the shoulders of the *balvardi*. The guns on the lower flank stood on an open platform, protected by a parapet of masonry with embrasures; behind them was a semicircular wall, having its concavity outwards, which supported the earth constituting the upper flank; and over this wall the guns on the platform of the *balvardi* fired *en barbette*, or over the parapet. Behind this circular wall were sometimes situated casemates, containing guns, which then formed a third battery between the levels of the other two. The walls supporting the ramparts of the place were occasionally strengthened by vertical or horizontal counter-arches. Maggi relates that such works were, in his day, to be seen in several of the cities of Tuscany; and that there was at Padua a strong one, which had been built in A. D. 1550, from a design given by San Micheli of Verona. Under the *gorge* or back of the *balvardo* was a vaulted gallery, the roof of which was supported on pillars, and by which a communication was made from one flank to the other. He observes that this gallery may also serve as a countermine; for, on abandoning the *balvardo*, he would have powder deposited in pits made on purpose under the piers: and these being blown up, there would be left a ditch between the enemy and the town.

Counterguards.

Places of arms,

and fausse-braye.

After speaking of the banks of earth which have been observed in some of the old ditches of fortresses, Castriotto proposes, in order to increase the strength of such places, to connect the banks together by a large *balvardo* built round each of the towers at the angles of the ancient circuit of wall. In the plan which he has given of a place thus fortified,[*] these works have a great resemblance to the counterguards in Vauban's Second and Third Systems; and the idea may be considered as the first step to the formation of large bastions in such situations. In the covert-way surrounding the ditch, the same engineer proposes to place circular redoubts, with loop-holes in the walls, as stations for a guard; and such redoubts seem to have been the originals of the places of arms, subsequently formed at the re-entering and salient angles of that part of the fortifications. Having given the dimensions of the great ditch and glacis from the writings of Cataneo and Tartaglia, he points out the advantages which would arise from continuing the glacis at its foot below the level of the ground, to form what may be called an advanced ditch; observing that it would impede the progress of the enemy in making the assault, and would prevent his retreat if repulsed. Castriotto observes that there then existed in France many places surrounded by what he calls a *fossa brea*, (*fausse-braye*,) or outer circuit; and from the view which he has given, it appears to have been simply a wall detached from the foot of the main rampart.

Rapid adoption of the Bastion System throughout Europe.

Its developement by Errard of Bar le Duc, the father of the modern Art of Fortification in France.

The inventions of the Italian engineers in the Art of Fortification must have been very early adopted in the North of Europe: for we find, that in the time of Charles V., Emanuel of Savoy, the General of that Emperor, built Hesdin near Amiens with spacious bastions, whose distances from each other seem to have been regulated by the range of muskets. And the citadel of Antwerp, which is thought to have been the first regular fortification constructed in that manner, was built in the reign of Philip II. of Spain. In the time of Errard, however, who wrote in A. D. 1594, we find that large bastions, or *boulevards*, as he sometimes designates them, had been generally introduced either as outworks in front of the round towers of ancient fortresses, or to supersede the latter entirely; and, in the designs which that engineer has given as then new, they always form part of the circuit, and are constructed at the angles of the polygon as in modern fortifications. But their flanks, which are double or triple, are short, and are protected by circular or rectangular orillons. Errard speaks[†] of ravelins and bastions as of detached works, added in front of the curtains between two small towers; and when the curtain is long, he proposes to have two such works, either separated from each other, or connected by a curtain, and he denominates the whole a *tenaille*, expressly stating it to be of use in affording room for the defenders, which was wanting in the ancient circuit. It is remarkable, however, that he has shown ravelins of the modern kind in only one of his own designs; and in that they appear to be without ditches, and to resemble merely re-entering places of arms. We may add to this brief account of the works of one who may be considered as the father of French military engineering, that he has given[‡] an example of a front of fortification, in which counterguards are traced in such a manner as to cover the faces of a large bastion: he does not, however, recommend them, alleging the expense of their construction, and the probability that the enemy might place artillery upon them for the purpose of breaching the inner wall. On the other hand, he proposes, in order to prolong the defence, that good retrenchments should be made in the interior of a bastion, or at its gorge, by a rampart formed either in a straight line or in the manner of a tenaille. Ravelins or bastions, connected by curtains, so as to form one or more fronts of fortification, as they are now called, and therefore resembling modern horn or crown works, are also recommended by Errard,[*] to serve as defences for a bridge, or to cover the suburb of a town.

Remarkable example of its early adoption in England.

Carisbrooke Castle.

The Italian system, which, nearly as soon as it can be said to have been formed, was, as we have seen, introduced into Flanders and France, appears to have been about the same time received in England; and, among the small number of military constructions which our Country can boast, it happens that one belongs to the first Age of modern Fortification. The example we allude to is exhibited in the works about Carisbrooke Castle in the Isle of Wight. That interesting fortress may pass for one of the most ancient in the Country, (even though we should not assent to the opinion of Dr. Stukely, that it was originally built by the Emperor Carausius,) since mention is made of it in the Saxon Annals. It is supposed to have been enlarged soon after the Conquest; and the grand entrance, on the Western side, was built during the reign of Edward IV. The old wall of the Castle is of a pentagonal form; it has a lofty keep on the North-East side; and besides the small towers at the angles, which are disposed with a salient angle to the front, there is, on the middle of each of the walls connecting them, a rectangular projection having one side parallel to the length of the wall, probably for the purpose of defending the faces of the collateral towers. In the time of Elizabeth the Castle was surrounded by fortifications, enclosing an area considerably greater than that within the ancient walls, and having the parapet on a much lower level than the summit of those walls. These fortifications are constructed on an irregular pentagon, with bastions at the angles; and on two of the fronts the flanks are simple and rectilinear, but on the others they are protected by rectangular orillons. The rampart is revetted with a stone wall; and in each of the retired flanks, which are perpendicular to the curtain, are two apertures, intended as embrasures for small pieces of artillery. On two of the fronts of fortification there is, between the flanks, a bank of earth in the form of a modern tenaille; and beyond the ditch, in what may have been a sort of re-entering place of arms, there still remains a small elevation of earth, of a semicircular form, apparently intended as a ravelin, or, as this kind of work was sometimes called, a half-moon. In the area between these fortifications and the Norman walls, are elevations of earth which appear to have served as traverses, and as cavaliers to give the defenders, in the manner of the works of that Age, a command over the neighbouring heights. On one of the bastions is inscribed the year 1568, and the works are said[†] to have been executed by an Italian engineer named Genebella, who was brought from Flanders for the purpose. Their great resemblance to the fronts of fortification in the System of Errard, who was contemporary with our illustrious Queen, may, with what has been before said, be considered as a proof, that in her days the new method of fortifying places was practised nearly all over Europe.

PART II.

MODERN SYSTEMS OF FORTIFICATION.

CHAPTER I.

General Description of a Modern Front of Fortification.

For the general appearance of modern fortresses. vide plate i. fig. 2.

Having briefly traced the History of the Art of Fortifying from the earliest Ages to the period at which the general adoption throughout Europe of the Bastion System may be said to have introduced and established all the most essential principles in the Modern Science of Defence; we may next proceed to give some account of the various forms of construction for fortresses which have been since practised or proposed. Before, however, we enter on this description, it will be proper, in order to render it more intelligible to the general reader, to explain the form of a rampart and parapet, and the nature of the works which constitute what is called a front of fortification. Fig. 1, plate ii. represents the plan of a front with its outworks; and fig. 4 is a profile or section taken on that part of the plan which is designated by the dotted line A B. A horizontal plane passing through this line in fig. 4, represents the plane of site or level of the country; and *a b c e i* is the mass of earth forming the rampart and parapet: the earth is procured by excavating the ground in front; and this excavation constitutes the main ditch, the profile of which is *v r s t*. The line *a b* is the interior slope of the rampart; and this is made gentle enough to permit the defenders to ascend or descend it on occasion with tolerable facility. The line *b n* is the *terreplein* of the rampart, or level space on which the troops and cannon are placed for the defence; and its breadth is from thirty-six to forty-two feet, to allow of a free circulation in rear of the guns when in battery. Its part *c n* is the banquette or step, on which the soldiers stand to fire over the parapet; and it has a slope *m c* towards the rear, the base of which is equal to twice its height. Again, *d e*, the height of the parapet, is so regulated as to procure sufficient cover for the men and guns upon the terreplein. When the fortifications are constructed upon a level plain, seven feet and a half suffice for this purpose. The superior slope *e f* of the parapet is directed as nearly as possible to the edge *t* of the opposite side of the ditch, in order that a man, when firing over the parapet, may without difficulty see the enemy there. The line *f i* is the exterior slope of the parapet, which being made of earth stands upon a base equal to its height, for the sake of stability. The thickness of a parapet at its upper surface is generally about eighteen feet, that the work may not be pierced by shot from the heaviest artillery. The *revetment*, or wall of masonry (*i r p*) supporting the rampart, is made of such solidity, that its resistance may be more than equal to the pressure of the earth above and behind it; and *o p* is the buttress or counterfort placed behind the revetment, to increase the strength of the latter. The buttresses are placed at distances from each other of fifteen or eighteen feet, reckoning from centre to centre, as is shown in fig. 5, which represents a portion of the ground plan of the masonry on both sides of the ditch. The height of the wall *i r* should be so great as to render escalade very difficult or impossible; and for this purpose thirty or thirty-five feet may suffice. Nevertheless, its top *i* is not allowed to rise above the level *l k* of the crest of the parapet of the covert-way: the reason for which is, that no part of the masonry should be discernible from the enemy's distant batteries, lest being breached from them, the parapet should fall, and thus expose the terreplein of the rampart.

Form of the different parts of works.

Vide plate ii. figs. 1 and 4.

Rampart.

Parapet.

Revetment, or sustaining wall.

Buttresses, or counterforts. Fig. 5.

Ditch.

From what has been said, it must be evident to the reader, that the depth of the ditch is almost a fixed quantity: since it must depend upon the necessary height of the *escarp*, which is the name given to the outer face of the rampart. This is particularly the case when the ditch is a dry one: but there is no such absolute necessity when the latter contains a depth of water equal to six feet, which is deemed sufficient to prevent the enemy from wading through it to the assault, or to surprise the place. The breadth of the ditch must, in a great measure, depend upon the nature of the soil. If dry, the least breadth it ought properly to have should be equal to once and a half the height of the rampart: in order that the rubbish of the breach may not extend across it, and furnish the enemy's sappers wherewith to commence their passage, after they have pierced through the wall *t s*, which terminates the ditch on the side next to the Country. It may be added, that a dry ditch, if very narrow and deep, opposes an almost insurmountable obstacle to the enemy when he would destroy the escarp: since it renders him unable, from the crest of the glacis, to see the wall sufficiently near the foot to allow a practicable breach to be made; or obliges him to form his batteries on the terreplein of the covert-way, in which situation they must be roofed, in order to secure his gunners against the hand-grenades which the defenders may shower on him from the parapet. In these circumstances the besieger would probably resort to mines, as the only means of effecting his purpose: but here again he might be opposed by expedients of a similar nature, of which we shall give a description in its proper place. If, however, the ditch be a wet one, and that the enemy cannot possibly drain it, the wider it can be made the better; as the difficulty of forming a fascine passage across it will augment in proportion to its width.

Covert-way.

The opposite side of the ditch is called the *counter-scarp*, to distinguish it from the escarp. This ought always to be supported by a masonry revetment *t r*, of more complicated: in order to screen at least a small portion of the artillery of fortresses from the sweeping ricochet fire, which his own practice had introduced; and to prolong the defence after a breach should be formed in the face of a bastion.

His First System.

The method which he seems generally to have followed in his constructions up to the year 1688, and which writers have denominated his First System, differs in many points of detail from that of Pagan. He makes the distance between the salient angles of the nearest bastions equal to three hundred and sixty yards; (See fig. 11.) and, in assigning this length to the side of the exterior polygon, he was influenced by the consideration that the range of the wall pieces, by which the defenders of the flanks were to oppose the construction of the enemy's counter-battery on the crest of the opposite glacis, was equal to about three hundred yards. For, thence taking off forty yards for the supposed breadth of the main ditch and the covert-way, there would remain two hundred and sixty yards for what is called the length of the *line of defence;* and to this adding one hundred yards for the face adjoining to the flank, on which the defenders were stationed, the front of fortification will be found of the length above-mentioned. Vauban's reason for making the faces of the bastions equal to about one hundred yards in length, was that, in the inferior polygons, there would then be sufficient breadth at the gorge to allow a free communication between the bastion and the interior of the place. He then traced the flanks in directions forming angles of about eighty-one degrees with the lines of defence, in order that the fires from thence might take in reverse the assailants when in the act of storming the breach made in the face of a collateral bastion. The length of the flanks must evidently depend on the angle at which the lines of defence intersect each other; and this was determined by letting fall from the middle of the side of the polygon, towards the interior, a perpendicular to that side, and making its length equal to one-sixth of the length of that side in all polygons greater than the pentagon. The extent of the flank thus became somewhat greater than that of the battery which the enemy could construct to dismount its guns: while the flanked angle of the bastion continually increasing with the number of sides in the polygon, the interior of that work became proportionally more capacious, and its faces less liable to the action of the ricochet. The above rules of construction also render the curtain joining the flanks of two bastions long enough to permit the defenders of those flanks to see the whole of the ditch between them; and it is therefore evident that no attempt of the enemy to surprise the enceinte can succeed.

The earlier modern engineers had, with a view of increasing the defence of the enceinte, surrounded it with a *fausse braie*, or attached parapet on a lower level than the principal one: but this work being subject to several defects, particularly to a plunging fire from the enemy's lodgements on the glacis, was superseded by the *tenaille*, an invention of Vauban, who constructed it, for the first time, when ordered to repair the citadel of Lille, for the purpose of covering the postern in the curtain, and defending the main ditch and the terreplein of the ravelin. He also directed the counterscarp towards the angle of the shoulder of the opposite bastion instead of drawing it parallel to the faces, as in Pagan's outline; by which he gained the advantage of laying open the whole of the ditch to the fire of the flank, which otherwise was in some polygons intercepted by the re-entering angle of the counterscarp. He augmented considerably the size of the ravelin; making its faces about equal in length to those of the bastions, and directing them to points taken on the bastions at ten yards from the shoulder-angles, in order to cover, in some measure, those shoulders from the fire of the enemy's counter-batteries at the salients of the ravelin. He made the re-entering places of arms more spacious than they were before; gave ten yards to the breadth of the covert-way; and placed traverses across the latter, at certain intervals, to increase its means of defence, and protect the men there from the effect of the ricochet.

His Second System.

Notwithstanding all these improvements in the System of fortifying, many ameliorations were yet requisite to keep pace with the ascendant which the attack was rapidly gaining over the defence. The numberless instances of capitulations being made as soon as a breach was practicable in the body of the place, owing to the unwillingness of Governors to risk the consequences of an assault, convinced Vauban that some contrivance must be resorted to, which would obviate the evils of dependence on a precarious retrenchment made during the siege. With a view to this object, when instructed to fortify Landau, he separated the bastions from the body of the place by a ditch about forty feet wide, in order that, after the breaching and capture of the bastions, the besieger might be compelled to recommence operations against the enceinte. The angles of the latter were fortified by small pentagonal towers of masonry, called tower bastions: (See fig. 12.) underneath which he contrived casemates for two guns in each flank, and bomb-proof barracks for the troops along the faces, besides powder-magazines in the centre. This mode of fortifying is distinguished by the name of *Vauban's Second System:* but Béfort is the only fortress besides Landau, where it has been executed. The System, although in some respects stronger than the preceding one, left nevertheless much room for improvement, of which Vauban seems to have been aware: for in fortifying Neu Brisack, he increased the size of the ravelin, and gave it a redoubt. (His Third System.) The tower bastions were likewise made larger; and the curtain which united them was broken inwards: (See fig. 13.) so as to form two small flanks, underneath which casemates for cannon were constructed, to cooperate with those of the tower bastions in the defence of the ditch. This assemblage of works constitutes what is commonly, but perhaps improperly, called *Vauban's Third System:* for that great engineer did not himself write on the fortification of places; nor does it appear that he ever professed to follow any exclusive method in his constructions; but rather that he always adapted the nature and disposition of his works to the circumstances of the surrounding ground. Both these latter Stystems, although calculated to prolong the defence, were of much too expensive a nature to admit of being frequently put in practice in any state. An opinion moreover has very generally prevailed, that the smoke from the priming would render it impossible to remain in the casemates during the firing of the guns, owing to the want of ventilation. To ascertain whether or not this prejudice was well founded, the French Convention, in the year 1793, ordered an experiment to be tried in them by General the Citizen Desnoyers. This was done in the presence of the Governor and all the Garrison Staff of Neu Brisack. The result proved that the casemates under the flanks of the tower bastions were perfectly serviceable, however briskly the fire might be kept up in them; and that the small ones under the curtain flanks were equally so, provided the gunners were relieved every quarter of an hour. In both cases, however, it appeared that loose powder ought to be substituted for tubes as priming; and that, for firing, slow match should be used in lieu of port-fire, the smell and smoke from the former being less offensive.

COEHORN.

For the sake of chronological exactness, we shall next notice Coëhorn's Systems, although their exclusive appropriateness to marshy soils might fully justify our speaking of them separately, without interrupting the present sketch of the progress of improvement in the Art of Fortification. Coëhorn was the Vauban of the United Provinces; and like his great contemporary, he excelled in the Science of Fortifying, and of attacking and defending places. His talents and achievements accordingly raised him to the highest posts in the service of his Country; and the works which he has executed justly entitle him to the admiration of the Military World. His ideas were adopted, with such modifications as localities rendered necessary, at Nimeguen, Breda, Manheim, Namur, and Bergen-op-Zoom. In A. D. 1685 he published his three methods for constructing the fortifications of places: the First, which he formed on a hexagon, was intended to be raised on a soil, underneath the surface of which water is supposed to be found at a depth of four feet; his Second System is formed on a heptagon, and is adapted to a soil three feet above water; and his Third is on an octagon traced on ground five feet above water. The principal aim which he had in view was both to cover and flank his works more effectually than had until his time been done; to deprive the enemy of the space necessary for his batteries, and of soil for his approaches in the dry ditches; and moreover to surround him with cross fires whenever, by dint of perseverance, he might have penetrated into the works.

His First System.

See fig. 14.

From the brief view which we are to give of the means employed to arrive at these ends, it will be evident to the reader that the reason why Coëhorn exclusively chose marshy soils for the sites of his Systems, must have been that he had the interests of his native land alone in view; and that he would have succeeded equally well in appropriating defences to localities of any kind, is manifest from the merit displayed in the construction of Fort William at Namur. In his First System he has a capital or interior bastion, the revetment of which is hidden from the enemy's first batteries by the unrevetted face of an exterior bastion. This unrevetted or low face has between it and that of the capital bastion a dry ditch, the surface of which is but six inches above the natural level of the water, by which means it is rendered impossible for the enemy to establish himself in this ditch without undergoing the laborious process of bringing soil with him from the rear for the purpose of cover. This dry ditch is defended by six guns in a casemate under the stone tower placed at each shoulder of the exterior bastion; and the tower being unconnected with the flank of the capital bastion, covers it completely without taking up any portion of its length. A vaulted and loop-holed gallery extends along the interior of the low exterior face underneath the banquette, and communicates with the casemate in the tower; there are numerous doors made in this gallery to facilitate the egress and ingress of sorties; and it is moreover partitioned off at every eighteen feet by strong doors, that it may be defended foot by foot. Another considerable advantage which it possesses, is that of serving as a gallery of mines, from whence any lodgement which the enemy might attempt upon the low unrevetted face may be destroyed. Besides these defences, the dry ditch has a palisade provided with numerous barrier gates, extending along the front of the escarp of the capital bastion; and the space thus enclosed is swept by two guns placed at each extremity, or near the shoulders of that bastion. A vaulted, loop-holed, half-buried communication passes along the capital of the dry ditch, from a gallery of mines at the back of the escarp of the capital bastion, to the gallery under the exterior face. This communication, or covered caponnière, being partly sunk under ground, is necessarily made cistern-like, owing to its being beneath the natural level of the water, which, when the defenders are obliged to abandon it, may be let in by means of a sluice to prevent its being of any service to the enemy. The stone tower before mentioned is separated from the dry ditch by a small wet one, twelve yards wide, defended by three guns placed behind a wall at its interior extremity. The communication over this ditch is by two bridges: one conducts to the space without, and the other to that within the palisades above mentioned. Another small wet ditch situated in front of the orillon, or stone tower, and of the flank which connects the latter with the curtain of the enceinte, serves as a harbour: it communicates with the main ditch by a covered passage for boats, rafts, &c. The dry ditch between the flanks of the capital and exterior bastion, is defended by four pieces of cannon placed in a casemate, which is formed in the part of the curtain joining those flanks: through this there is a postern communicating with all the lower works.

The main ditch is defended by three flanks: that of the capital bastion; that of the inferior bastion; and that of the tenaille, or, as it may be called, the lower curtain. The latter flank is kept lower than the curtain and face with which it is connected, in order to allow the fires from the works in its rear to pass over it; and the curtain and face have a greater relief given to them, the first that it may the better cover the principal curtain, and the second that it may more effectually screen the low flank. A communication is made into the space between the two curtains, by means of a postern in the middle of the enceinte. The capital ravelin is revetted; and in front of it is a dry ditch, which is covered by the unrevetted rampart of the exterior ravelin. This dry ditch is defended by the faces of the capital and lower bastion, by the upper part of the tower, and by the double fire from the *coffers* or splinter proofs, which are formed across its extremities, near the main ditch. It moreover derives a defence from a covered caponnière joining the salient angles of the exterior and interior ravelins, similar to that already described, in the dry ditch of the bastion; and from a row of palisades extending along the foot of the escarp of the exterior ravelin. The two splinter proofs are screened from an attack by storm, by a small wet ditch, which is defended by a loop-holed gallery under the face of the lower ravelin. This loop-holed gallery serves as a communication into the dry ditch of the ravelin, for which purpose doors are made at its extremities; and a postern placed under the face of the capital ravelin completes the communication to the interior of the latter. The passage from behind the splinter proof to the space enclosed between the palisades and the escarp, is by a small bridge. There is likewise a postern passing under the capital of the revetted or interior ravelin into the caponnière. The three flanks which defend the main ditch can only be counter-battered from the earthen counterguards which cover the bastions: but as these consist only of a parapet and a double banquette, the enemy would be unable, from want of room, to establish a battery on them. The covert-way is of a great breadth, (seventy-two feet,) and it slopes gradually inwards to the water's edge. The faces of the re-entering places of arms are provided with loop-holed coffers or splinter proofs, for the defence of the glacis by a double and grazing fire. A loop-holed wall serves as a redoubt to the place of arms; and palisades placed along the branches, faces, traverses, and in front of the above-mentioned redoubt, complete the defensive dispositions of the covert-way.
